A common finding of HF is increased cardiac workload. Four major determinants contribute to LV workload: preload, afterload, contractility, and HR.

Preload

Preload describes forces acting on the *venous* side of the circulation affecting myocardial wall tension. The volume is maximal when filling finishes at the end of diastole (LV end-diastolic volume). An increased volume raises the pressure within the ventricle (LV end-diastolic pressure), which in turn increases the "stretch," or wall tension, of the ventricle. Peripheral venous dilation and decreased peripheral venous volume diminish preload, whereas peripheral venous constriction and increased peripheral venous volume increase preload.

Elevated preload can aggravate HF. Rapid administration of blood plasma expanders and osmotic diuretics or administration of large amounts of sodium or sodium-retaining agents increases preload. A malfunctioning aortic valve (aortic insufficiency), resulting in regurgitation of blood back into the left ventricle, can increase the volume of blood that must be pumped. A malfunctioning mitral valve (mitral regurgitation) can cause retrograde ejection of blood from the

left ventricle back into the left atrium, with a resultant decrease in CO. In patients with systolic failure, ventricular blood is ejected less efficiently because of a hypofunctioning left ventricle; the volume of blood retained in the ventricle is thus increased, and preload becomes elevated. In HFpEF with a stiffened left ventricle, relatively small increases in end-diastolic volume from sodium and water overload can lead to exaggerated increases in end-diastolic pressure.

Afterload

Afterload is the tension developed in the ventricular wall as contraction (systole) occurs. This tension is affected by intraventricular pressure, ventricular diameter, and wall thickness. Afterload is affected by the systemic vascular resistance (SVR) or the impedance against which the ventricle must pump and is estimated by arterial blood pressure (BP). HTN, atherosclerotic disease, or a narrow aortic valve opening increases arterial impedance (afterload), thereby increasing the workload of the heart. HTN is a major factor in the development of both HFrEF and HFpEF. The Framingham group found that 75% of patients who developed HF had a history of HTN.[13] The risk of developing HF was six times greater in patients with hypertension versus that in patients with normotension.

Cardiac contractility

The terms *contractility* and *inotropic state* are used synonymously to describe the myocardium's ability to develop force and shorten its fibers independent of preload or afterload. Myocardial contractility is decreased when myocardial fibers are diminished or poorly functioning, as may occur in patients with primary cardiomyopathy, valvular heart disease, CAD, or after an MI. Defects in contractility play a major role in systolic HF but are not a factor for diastolic dysfunction. Drugs such as β-adrenergic blockers or anthracyclines precipitate HF by decreasing myocardial contractility.

Heart rate

An increased HR is a reflex mechanism to improve CO as EF declines. The sympathetic nervous system is the major mediator of this response. The workload and energy demands of a rapid HR ultimately place strain on the heart and can eventually worsen HF.

Pathophysiology

When the heart begins to fail, the body activates several complex compensatory mechanisms in an attempt to maintain CO and oxygenation. These include increased sympathetic tone, activation of the renin–angiotensin–aldosterone system (RAAS), sodium and water retention, and other neurohormonal adaptations, which lead to cardiac “remodeling” (ventricular dilatation, cardiac hypertrophy, and changes in LV shape). The consequences of these adaptive mechanisms can create more harm than good (**Fig. 14-2**). The relative balance of each of these adaptive processes varies depending on the type of HF (systolic vs diastolic dysfunction) and from patient to patient with the same disorder. An understanding of the potential benefits and adverse consequences of these compensatory mechanisms is essential to understanding the signs, symptoms, and treatment of HF.[14]

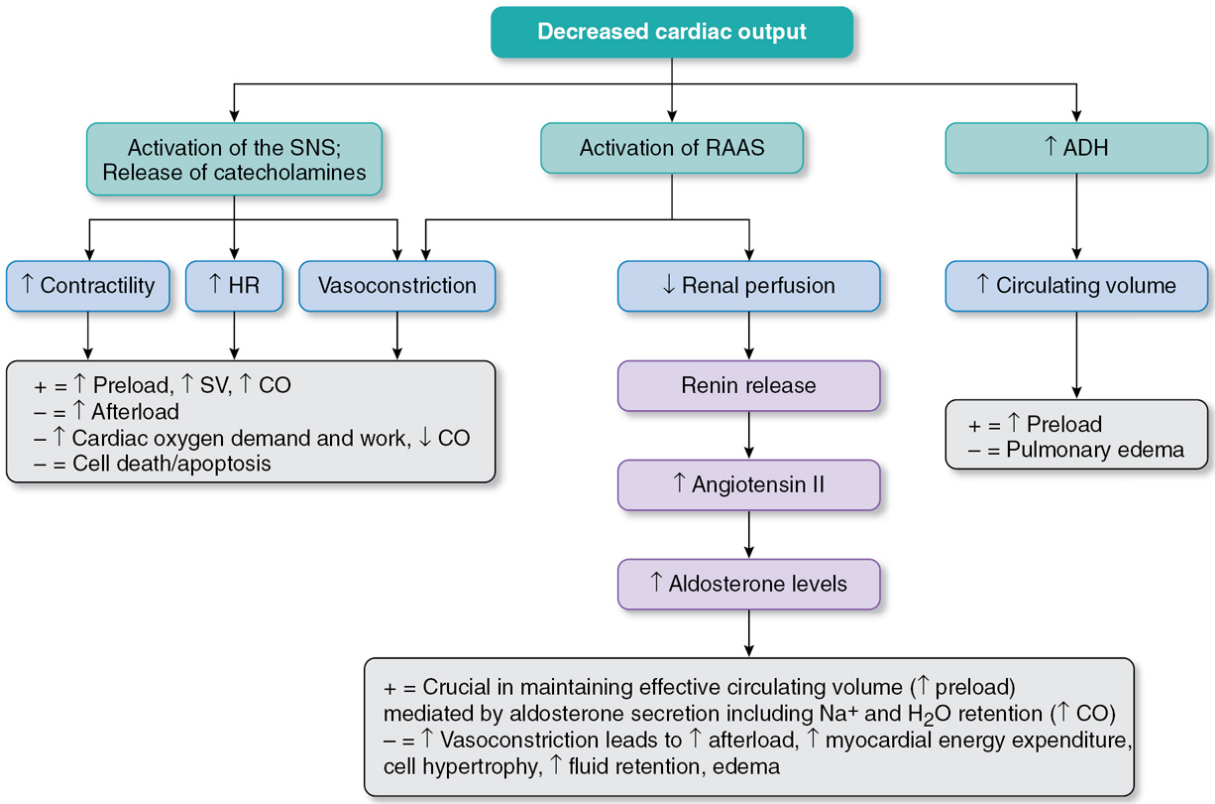

Figure 14-2 Adaptive mechanisms in systolic heart failure. +, beneficial results; –, negative (detrimental) effects; ADH, antidiuretic hormone; CO, cardiac output; HR, heart rate; H_2O, water; Na^+, sodium; RAAS, renin–angiotensin–aldosterone system; SNS, sympathetic nervous system; SV, stroke volume.

SYMPATHETIC (ADRENERGIC) NERVOUS SYSTEM

The body's normal physiologic response to a decreased CO is generalized activation of the adrenergic (sympathetic) nervous system, as evidenced by increased circulating levels of norepinephrine (NE) and other catecholamines. The inotropic (increased contractility) and chronotropic (increased HR) effects of NE initially maintain near-normal CO and perfusion of vital organs such as the central nervous system (CNS) and myocardium. Adverse consequences of NE activation include impaired sodium excretion by the kidneys, restricted ability of the coronary arteries to supply blood to the ventricle (myocardial ischemia), increased

arrhythmias, hypokalemia, and oxidative stress triggering cell death (apoptosis).

Chronic high levels of catecholamines are harmful to the heart because they decrease β_1-receptor sensitivity and reduce β_1-receptor density on the surface of myocardial cells by 60% to 70% in severe HF.[15–20] The normal ratio of β_1- to β_2-receptors in the heart is ~80:20. As a response to overstimulation, this balance is shifted to a ratio of ~70:30 in the failing myocardium by downregulation of β_1-subtype receptors. This selective downregulation of β_1-receptors is accompanied by "uncoupling of the β_1- and β_2-receptor activity," whereby the number of β_2-receptors is unchanged, but the responsiveness of these receptors can be reduced by 30%.[15] Over time, this leaves the myocyte less responsive to adrenergic stimuli and further decreases contractile function. β-Blockers cause the upregulation of the downregulated β_1 receptors and the resensitization of the uncoupled β_2-receptors, protecting the heart from the deleterious effects of catecholamines.[21]

Alterations in sympathetic adrenergic receptors are partially determined by genetic phenotype. Among African American patients with HF, a disproportionately high incidence of polymorphisms for variants of the β_1-receptor that are associated with increased function is seen. In addition, the combined presence of a variant of the β_1-receptor (β_1Arg389) and α_{2C}-adrenergic receptor (α_{2c}Del322–325) results in adrenergic overstimulation and increases the risk of HF. These combined defects are found less often in Whites, perhaps partially explaining a higher incidence of HF in African Americans. A better understanding of α- and β-receptor phenotypes may someday lead to improved prevention and treatment of HF.[22]

RENAL FUNCTION AND THE RENIN–ANGIOTENSIN–ALDOSTERONE SYSTEM

The reduced CO in HF leads to the stimulation angiotensin II, which is a potent vasoconstrictor. Angiotensin II is also a potent stimulator of the sympathetic nervous system, which increases SVR. Renal

vascular resistance is increased, and the glomerular filtration rate (GFR) is decreased. As the GFR decreases, more sodium and water are reabsorbed. A diminished effective circulating plasma volume and angiotensin II also stimulate the release of antidiuretic hormone (ADH) from the pituitary, resulting in the retention of free water in the collecting ducts.

The kidney releases renin when renal perfusion pressure is decreased. Renin converts *angiotensinogen* into *angiotensin I.* Angiotensin I is metabolized to *angiotensin II*, under the influence of angiotensin converting enzyme (ACE) (see **Fig. 14-2**). Angiotensin II has multiple effects favoring sodium and water retention. Its vasoconstricting effect decreases GFR, and it stimulates the adrenal glands to secrete aldosterone, which increases sodium reabsorption. Angiotensin II stimulates increased synthesis and release of vasopressin, thereby increasing free water retention and stimulation of thirst centers in the CNS. Finally, angiotensin II stimulates NE release. The net result of decreased renal perfusion is detrimental. Increased sodium and water retention increases preload, whereas angiotensin II–induced vasoconstriction increases SVR and afterload.

A chronic excess of aldosterone causes fibrosis in the myocardium, kidneys, and other organs.[23] Thus, aldosterone promotes remodeling of organs and fibrosis independent of angiotensin II.

OTHER HORMONAL MEDIATORS

Endothelins

Several other regulatory hormones and cytokines have been identified as playing a role in the pathogenesis and adaptation to HF. The first of these are the endothelins.[24,25] Endothelin-1 (ET-1) is the most active. ET-1 is synthesized by vascular and airway smooth muscle, cardiomyocytes, leukocytes, and macrophages. Serum concentrations of ET-1 are elevated in HF, pulmonary HTN, MI, ischemia, and shock, and cause vasoconstriction, potentiation of cardiac remodeling, and decreased renal blood flow (RBF). Although

the effects of ET-1 are detrimental in HF, its pharmacology is complex and dependent on the relative balance of two distinct G protein–coupled receptor subtypes referred to as ET_A and ET_B. As illustrated in **Table 14-2**, ET-1 can elicit opposing effects from each receptor, with the net effect being dependent on the relative density of the two receptors.

Table 14-2
Biologic Effects of Endothelin-1

Organ System	ET_A Receptor Effects	ET_B Receptor Effects	Other Effects
Blood vessels	Potent vasoconstrictor	Vasodilation mediated through nitric oxide and prostacyclin release	
	Collagen deposition		
Heart	Hypertrophy and remodeling		↑ HR
			+/– Inotropic effects
Lungs	Bronchoconstriction		
Kidney	Afferent and efferent vasoconstriction	Natriuresis and diuresis	
	Decrease in RBF and GFR		
Neuroendocrine			Release of catecholamines, renin, aldosterone, and ANH

ANH, atrial natriuretic hormone; ET_A, endothelin A; ET_B, endothelin B; GFR, glomerular filtration rate; HR, heart rate; RBF, renal blood flow; +/–, positive/negative.

From Ergul A. Endothelin-1 and endothelin receptor antagonists as potential cardiovascular therapeutic agents. *Pharmacotherapy*. 2002;22(1):54–65. Reprinted by permission of John Wiley & Sons, Inc.

Possible future therapeutic agents could be specific inhibitors of one or more of the enzymes to prevent activation of ET-1. Alternatively, selective inhibitors of ET_A receptors could shift responses toward the favorable aspects of ET_B receptor activation. Bosentan and tezosentan are nonselective dual ET_A/ET_B antagonists. Bosentan has the U.S. Food and Drug Administration (FDA) approval for the treatment of pulmonary HTN.

Natriuretic peptides

NPs are a family of peptides containing a common 17–amino acid ring. A-type NP, previously referred to as atrial NP or atrial natriuretic factor, is secreted by the atria in response to dilatation. Similarly, B-

type natriuretic peptide (BNP) is produced by the ventricular myocardium in response to elevations of end-diastolic pressure and volume. Type-C natriuretic peptide (CNP) is secreted by the lungs, kidneys, and vascular endothelium in response to shear stress. Collectively, the NPs are considered to be a favorable form of neurohormonal activation. Among their positive attributes are antagonism of the renin–angiotensin system, inhibition of sympathetic outflow, and ET-1 antagonism. The net effect is peripheral and coronary vasodilation decreasing preload and afterload. As their name implies, they also have diuretic or natriuretic properties, with improved RBF and glomerular filtration resulting from afferent arteriolar dilation and, possibly, efferent arteriolar constriction. Sodium reabsorption is blocked in the collecting duct owing to indirect aldosterone inhibition. NPs also inhibit vasopressin secretion and block salt appetite and thirst centers in the CNS, which contributes to diuresis. CNP has minimal diuretic properties.[26]

The BNP precursor is cleaved to produce the biologically active C-terminal fragment (BNP) and an inactive N-terminal fragment (NT-proBNP). Plasma level measurement of either BNP or NT-proBNP can be used as a biologic marker to differentiate HF-induced dyspnea from other causes of respiratory distress.[27–29] BNP levels <100 pg/mL usually indicate absence of HF, whereas levels >400 pg/mL are highly indicative of HF. However, the interpretation of BNP levels between 100 and 400 pg/mL can be challenging because elevated levels are also associated with renal failure, pulmonary embolism, pulmonary HTN, and chronic hypoxia.[30] Higher concentrations correlate with the severity of HF. Clinical resolution of symptoms is often accompanied by a decline in BNP concentration. The revised cutoff values for diagnosing HF according to NP levels in the ambulatory setting are ≥35 pg/mL for BNP and ≥125 pg/mL for NT-proBNP; and in the hospital setting are ≥100 for BNP and ≥300 pg/mL for NT-proBNP.[4]

Natriuretic hormone analogs or inhibitors of their metabolism have been investigated for drug therapy of HF. Nesiritide is a recombinantly produced human BNP approved by the FDA for IV management of acute HF exacerbations in hospitalized patients, but

it is no longer used in practice.[31,32] Downregulation of NP receptors, however, occurs during chronic HF, reducing the protective benefit of their actions and, possibly, limiting their usefulness as therapeutic entities.

Vasopressin receptor antagonists

Volume overload is associated with increased hospitalization. The potent vasoconstrictor ADH (arginine vasopressin) is inappropriately elevated in HF. Early studies with tolvaptan (selective vasopressin subtype V_2 receptor antagonist) demonstrated improvement in congestive symptoms of HF and overall hemodynamic profile but no improvement in long-term outcome.[33–35] Because long-term mortality benefits are lacking and the cost of the drug is high, the use of tolvaptan is restricted to patients with hypervolemic hyponatremia associated with HF despite fluid restriction and diuretic use.

Calcium sensitizers

Calcium sensitizers represent another class of drugs investigated for the treatment of acute decompensated heart failure (ADHF). They exert positive inotropic effects by stabilizing the calcium–troponin C complex and facilitating actin–myosin cross-bridging without increasing myocardial consumption of adenosine triphosphate.[36] Levosimendan, the prototype for this drug class, has a dual mechanism of action to increase myocardial contractibility and induce vasodilation. Unlike other inotropic agents, it does not affect the intracellular calcium concentrations and, therefore, has a lower potential for proarrhythmia. The safety and efficacy of levosimendan in ADHF has been evaluated in placebo-controlled trials and in comparative trials with dobutamine. In patients with decompensated HF, levosimendan significantly reduced the incidence of worsening HF and improved hemodynamic indices.[37–39] In addition, mortality was lower in the levosimendan group. These trials, however, were not powered to show a difference in mortality as an end point. A subsequent trial comparing levosimendan with dobutamine in ADHF, designed to confirm the beneficial effects on morbidity and mortality,

did not reduce all-cause mortality, which contrasts with earlier studies.[40] The most common adverse effects associated with levosimendan are headache and hypotension. Currently, levosimendan is approved in Europe for ADHF.

CARDIAC REMODELING

Progression of HF results in *cardiac remodeling*, characterized by changes in the shape and mass of the ventricles.[40] The three primary manifestations of cardiac remodeling are chamber dilatation, LV myocardial hypertrophy, and a resulting spherical shape of the left ventricle (**Fig. 14-3**). Cardiac remodeling, which starts before the appearance of clinical symptoms, contributes to the progression of the disease.

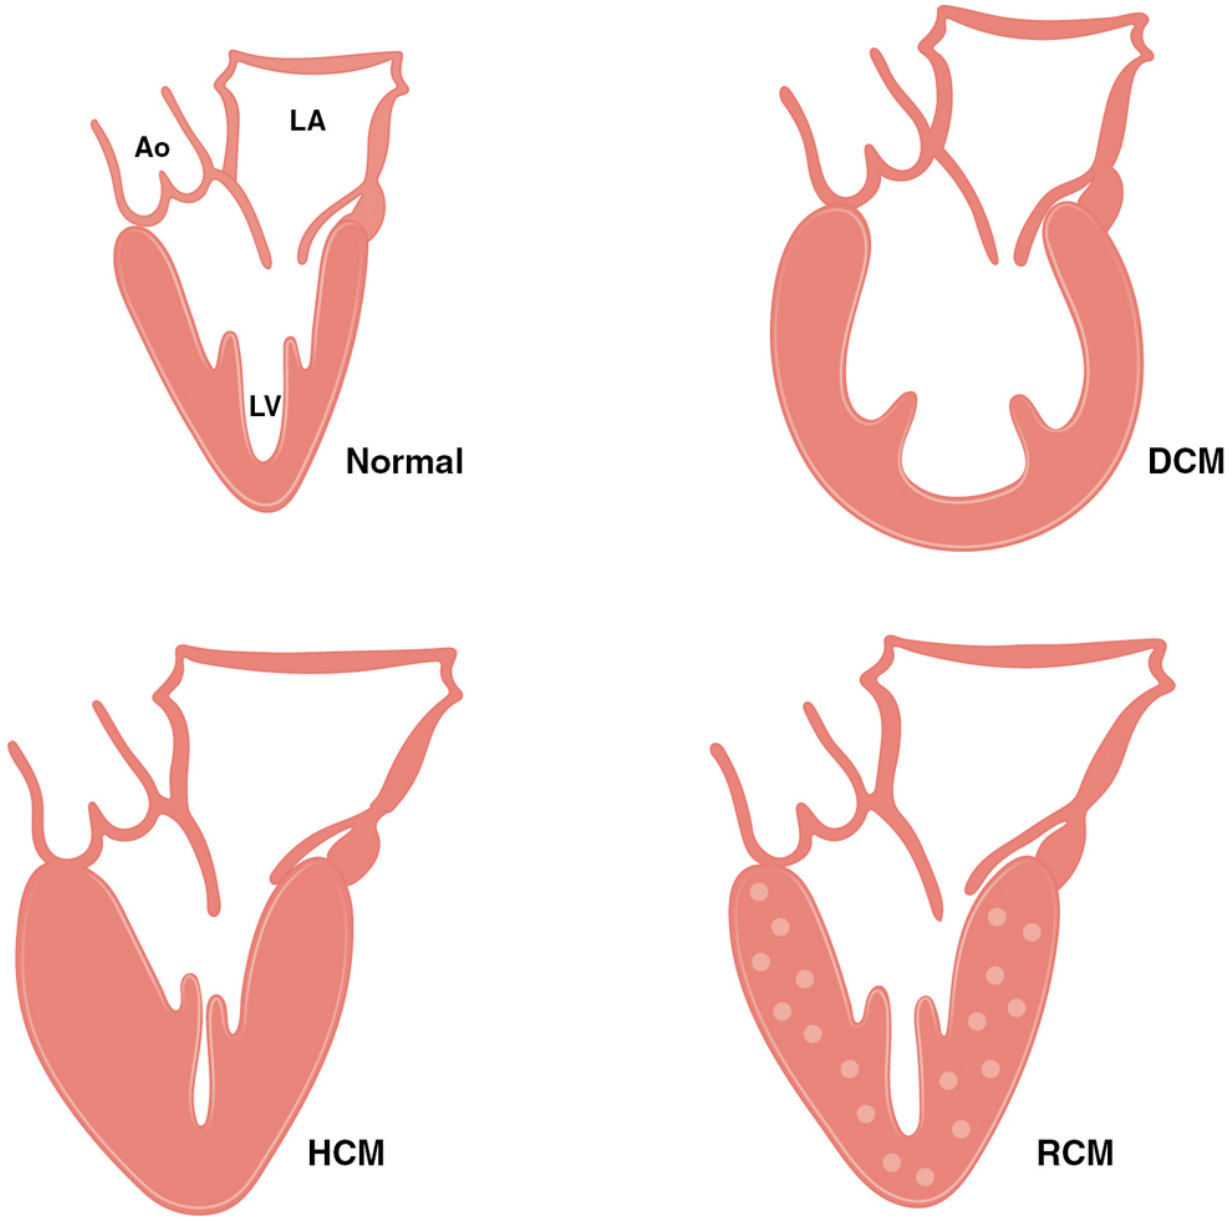

Figure 14-3 Cardiac remodeling. Dilated cardiomyopathy (DCM) results in thinning of the left ventricular walls and a decrease in systolic function; in hypertrophic cardiomyopathy (HCM), there is a marked thickening of the left ventricular walls leading to diastolic or systolic failure; and in restrictive cardiomyopathy (RCM), the left ventricular walls may be normal, hypertrophic, or slightly dilated, resulting in a decrease in diastolic compliance. Ao, aorta; LA, left articular; LV, left ventricular. (Adapted with permission from Topol EJ, Callif RM, Prystowsky EN, et al, eds. *Textbook of Cardiovascular Medicine*. 3rd ed. Lippincott Williams & Wilkins; 2006.)

Cardiac dilatation

Cardiac dilatation results from hypervolemia. End-diastolic volume increases, myocardial fibers are stretched, and the ventricle(s) become dilated. In a healthy heart, the end-diastolic volume is 110 to 120 mL. With an EF of 60%, the SV would be 70 mL, leaving an end-systolic residual volume in the ventricle of 40 to 50 mL. With HFrEF, the end-diastolic volume increases resulting in an enlarged heart. Cardiac dilatation is less evident in HFpEF because normal contractility is maintained, and the stiffened left ventricle is resistant to filling and less likely to dilate (see **Fig. 14-3**).

Frank–Starling curve

The Frank–Starling curve (**Fig. 14-4**) demonstrates a curvilinear relationship between LV myocardial muscle fiber "stretch" (wall tension) and myocardial work. As the stretch increases, the volume of blood ejected (SV) with each contraction increases. In systolic HF, the work capacity for any degree of stretch is diminished. A simple analogy is drawn using a balloon. The greater amount of air blown into a balloon, the more it stretches and, if released, the farther it flies around a room. As the balloon gets old, it loses its elasticity and thus has less recoil. Similarly, dilatation of the ventricles initially may serve as an effective compensating mechanism in systolic failure but becomes inadequate as the elastic limits of the muscle fibers are reached. HR also increases to maintain CO when SV is low. The disadvantage of cardiac dilatation is increased myocardial oxygen demand. Theoretically, as cardiac dilatation progresses beyond a certain point, CO could decrease (as visualized on the descending limb of the Starling curve), but this is rarely observed clinically.

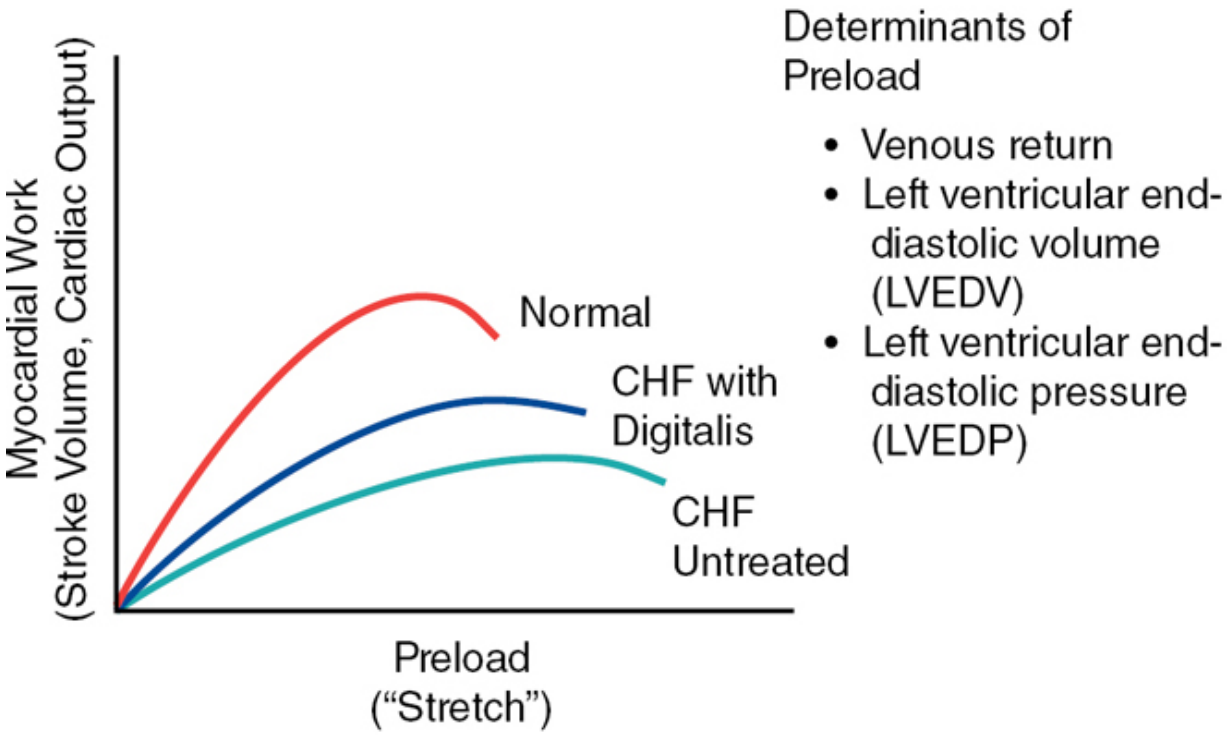

Figure 14-4 Representation of the Frank–Starling ventricular function curve.

Cardiac hypertrophy

Cardiac hypertrophy represents an absolute increase in myocardial muscle mass and muscle wall thickness (see **Fig. 14-3**). This is analogous to increased skeletal muscle mass in response to weightlifting. Cardiac hypertrophy should not be confused with cardiac dilatation.

FUNCTIONAL LIMITATION CLASSIFICATION AND STAGES OF HEART FAILURE

New York Heart Association classification

The NYHA classification scheme identifies four categories of functional disability associated with HF. Patients in class I are well compensated with no physical limitations and lack symptoms with ordinary physical activity. In class II, ordinary physical activity results in mild symptoms and imparts slight limitations on exercise tolerance. Patients in class III are comfortable only at rest; even less

than ordinary physical activity leads to symptoms. In class IV, symptoms of HF are present at rest and no physical activity can be undertaken without symptoms. Determination of class is subjective and will vary among observers.

A shortcoming of the NYHA classification scheme is that it does not include asymptomatic individuals who are at high risk for developing HF and may benefit from preemptive lifestyle changes and drug therapy.[41]

The 2001 ACC/AHA guidelines introduced a staging system that can be used in conjunction with the NYHA classifications.[42] Although this staging has been uniformly adopted by different societies, it is not widely used by nonspecialists or clearly understood by patients. Furthermore, staging gives the impression that there is only one direction for patients to progress (A–D). With this framework, the staging terminology has been revised[4] to add clarity and applicability. The new stages of HF include At risk for HF (former stage A), Pre-HF (former stage B), HF (former stage C), and Advanced HF (former stage D) (**Fig. 14-5**).

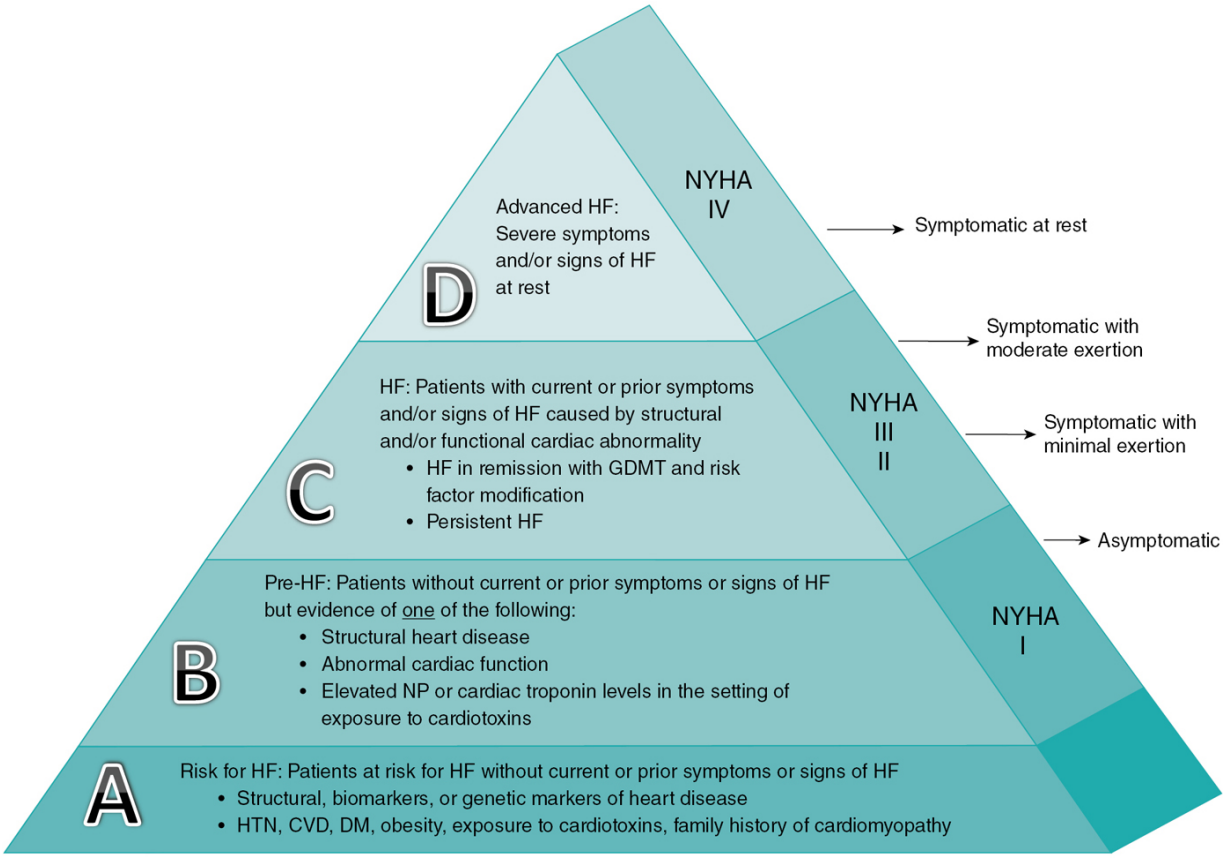

Figure 14-5 Staging and New York Heart Association (NYHA) classification of heart failure. (Data from Heidenreich PA, Bozkurt B, Aguilar D, et al. 2022 AHA/ACC/HFSA guideline for the management of heart failure: a report of the American College of Cardiology/American Heart Association Joint Committee on clinical practice guidelines. *J Am Coll Cardiol*. 2022;79(17):e263–e421.)

In addition, staging can improve with GDMT. The intent of this change was to simplify the staging so that it is easier to translate to patients. The Pre-HF terminology raises awareness for screening and prevention treatment strategies such as precancer screening. It also allows clinicians to prescribe treatment strategies such as SGLT2 inhibitors for patients at risk for HF and Pre-HF.

The writing committee also introduced new terminology on clinical trajectories.[4] The new emphasis is on “persistent” HF rather than on “stable” HF. Even patients who are less symptomatic and not deteriorating are at significant risk for death (22% mortality at 5

years). The emphasis has also shifted to HF in “remission” rather than in “recovered HF.” Patients with HF with a resolution of signs/symptoms of HF and previous structural/functional heart disease typically do not recover. This is supported by the results of TRED-HF trial[43] that showed that withdrawal of pharmacological treatment for heart failure in patients with recovered dilated cardiomyopathy (TRED-HF) resulted in a relapse in about 40% of patients, suggesting that improvement in LV function and resolution of symptoms represent remission rather than complete recovery for most patients.

In the new universal definition, the writing committee also extended the signs and symptoms of HF. In clinical trials, validation of HF diagnosis historically relies on criteria based on signs and symptoms such as Framingham criteria or episodes of care (hospitalizations and emergency department [ED] visits). But this criterion lacks specificity because similar symptoms can be caused by kidney disease or lung disease. Therefore, typical as well as less typical symptoms and specific exam findings are added for clarity.[4]

Overview of Treatment Principles

The guidelines recommend that most patients with HFrEF should receive GDMT including an angiotensin converting enzyme inhibitor/angiotensin receptor blocker (ACEI/ARB) or an ARNI, a β-adrenergic blocker, aldosterone receptor antagonist, and an SGLT2 inhibitor. Clinical algorithms from the ACC/AHA guidelines are found in **Figures 14-6** and **14-7**. Diuretics are recommended for patients with congestion. The combination of hydralazine and nitrate should be considered in Black patients with symptoms despite receiving other GDMTs or in patients unable to tolerate an ACEI or ARB. Digoxin is potentially beneficial in symptomatic patients with HFrEF already receiving optimal medical therapy to decrease HF hospitalizations. In patients who are receiving maximally tolerated doses of β-blockers with an HR of >70 bpm, addition of ivabradine can be considered.

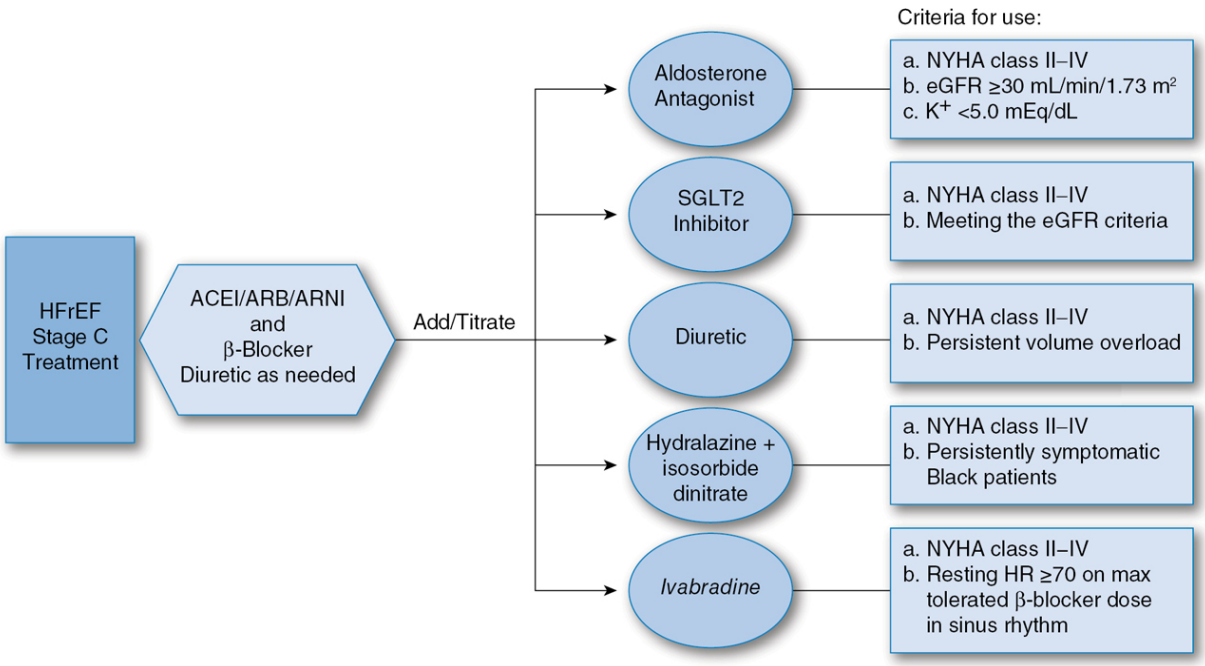

Figure 14-6 Treatment algorithm for HFrEF stage C. ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blockers; ARNI, angiotensin receptor–neprilysin inhibitor; eGFR, estimated glomerular filtration rate; HFrEF, heart failure with reduced ejection fraction; HR, heart rate; NYHA, New York Heart Association; SGLT2, sodium–glucose cotransporter-2.

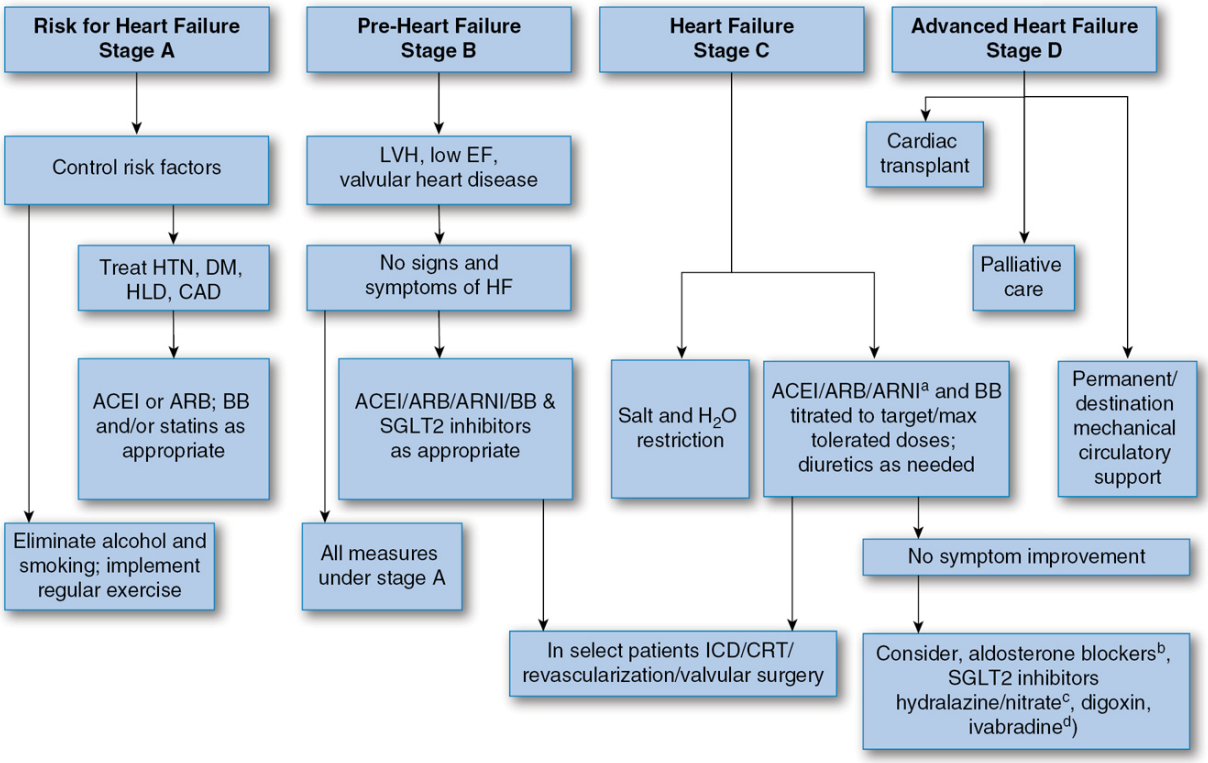

Figure 14-7 Stages in the development of heart failure and recommended therapy by stage. ACEI, angiotensin converting enzyme inhibitors; ARB, angiotensin receptor blockers; ARNI, angiotensin receptor–neprilysin inhibitor; BB, β-blockers; CAD, coronary artery disease; CrCl, creatinine clearance; DM, diabetes mellitus; EF, ejection fraction; HLD, hyperlipidemia; HTN, hypertension; ICD, implantable cardioverter-defibrillator; LVH, left ventricular hypertrophy; SGLT2, sodium–glucose cotransporter 2 inhibitors.

[a]New York Heart Association (NYHA) II or III who tolerate angiotensin converting enzyme inhibitors/angiotensin receptor blockers (ACEI/ARB) with adequate blood pressure (BP) and no hx of angioedema; replace with angiotensin receptor–neprilysin inhibitor (ARNI) to further reduce morbidity and mortality, must wait at least 36 hours from the last dose of ACEI.

[b]New York Heart Association (NYHA) II to IV unless est. creatinine clearance (CrCl) <30 mL/minute and serum potassium >5.0 mEq/L.

[c]New York Heart Association (NYHA) III or IV in Black patients.

[d]New York Heart Association (NYHA) II or III, left ventricular ejection fraction (LVEF) ≤35%, maximally tolerated dose of β-blocker, sinus rhythm, and heart rate

70 bpm or greater.

Despite robust evidence of HF medications in reducing mortality and morbidity, the findings from the **Cha**nge the **Ma**nagement of **P**atients with **H**eart **F**ailure (CHAMP-HF)[44] registry demonstrated major gaps in use and dosing of GDMT. Among eligible patients for GDMT (27%), 33% were not on a β-blocker and 67% were not prescribed aldosterone antagonists (AAs). Even when patients received HF medications, they were not on target doses and only 1% of patients with HFrEF were receiving target doses of indicated therapies.

Many barriers in clinical practice such as renal function, hypotension, and hyperkalemia make it challenging to initiate or uptitrate GDMT. The 2021 update to the 2017 ACC expert consensus decision pathways for optimization of HF treatment[45] addresses strategies to overcome treatment barriers, improve adherence, manage comorbidities, decide when to refer patients for advanced HF therapies, and provide team-based care. The authors provide detailed scenarios for treating HFrEF with β-blockers, ACEIs, ARBs or ARNI, and SGLT2, as well as tools to evaluate the titration and maintenance of medications.

The goals of therapy for HF are to abolish disabling symptoms, avoid complications such as arrhythmias, improve the quality of life, and prolong survival. Short of a heart transplant, none of the treatment measures are curative.

Nonspecific medical management of HF includes addressing cardiovascular (CV) risk factors, correcting underlying disease states (HTN, ischemic heart disease, arrhythmias, lipid disorders, anemia, or hyperthyroidism), performing moderate physical activity as tolerated, undergoing immunization with influenza and pneumococcal vaccines, and discontinuing possible drug-induced causes. The role of NPs, endothelin inhibitors, vasopressin receptor antagonists, and calcium sensitizers has been investigated. Non-digitalis inotropic agents and tumor necrosis factor-α (TNF-α) inhibitors, although theoretically valuable, have yielded disappointing results and significant complications, including arrhythmias and

increased mortality rates. Myosin activators (such as omecamtiv mecarbil and danicamtiv) represent another potential drug target in HF.[46]

Treatment of HFpEF historically has been less well defined, but recent data with sacubitril-valsartan and empagliflozin have shown positive findings.[47,48] A sodium-restricted diet and diuretics are indicated for symptomatic relief of SOB or edema. Because these patients typically present with comorbid conditions (atrial fibrillation [AF], HTN, diabetes mellitus, and CAD), treatment of comorbidities with available therapies should aim to decrease CV events and improve survival.[11] The guidelines[2,3,11] suggest a IIb class of recommendation consideration for angiotensin receptor antagonists and mineralocorticoid antagonists.

The new 2022 HF guidelines[2] have included both SGLT2 inhibitors and ARNI for the management of HFpEF to decrease HF hospitalizations: A 2a and 2b class of recommendation for SGLT2 inhibitors and ARNI, respectively.

The 2022 HF guidelines[2] also provide treatment recommendations for heart failure with ejection fractions between 41% and 49% considered “mildly reduced ejection fractions” (HFmrEF). These recommendations are based on secondary analysis of previous HF trials. SGLT2 inhibitors have a stronger recommendation whereas ARNI, ACEi, ARB, MRA and β-blockers are considered weaker recommendations in HFmrEF. In clinical practice, this category of patients are frequently treated similar to patients with HFrEF. Periodic assessment of LV function should be considered to determine the course of disease.

PHYSICAL ACTIVITY

Patients should be encouraged to exercise to maintain physical conditioning. Treatment goals include prolonging life and improving quality of life. The results of the Effects of Exercise Training on Health Status in Patients with Chronic Heart Failure (HF-ACTION)[49] trial showed that a highly structured exercise program in patients with HF did not reduce all-cause mortality or all-cause hospitalization

when compared with patients who were getting the usual care in which exercise was simply encouraged. However, according to the HF-ACTION substudy, the structured exercise training program improved the overall Kansas City Cardiomyopathy Questionnaire (KCCQ) score (a test that includes questions on physical limitations, symptoms, quality of life, and social limitations). The improvement occurred early on and was sustained for 3 years. The ACC/AHA HF guidelines[2,11] recommend exercise training as safe and effective for patients with HF who are able to participate in symptom control.[1,11] However, during acute exacerbations, bed rest and restricted physical activity decrease the metabolic demands and minimize gravitational forces contributing to edema. Renal perfusion is increased in the prone position, resulting in diuresis and mobilization of fluid.

SODIUM-RESTRICTED DIET

Dietary indiscretion (high salt intake) is often cited as the cause of HF exacerbations and hospital admissions. Several observational studies have demonstrated associations between lower dietary sodium intake and reduced hospitalizations and mortality.[50,51] In contrast, several randomized trials imply that dietary sodium restriction in patients with CV diseases may be deleterious. One of the largest meta-analysis in patients with HFrEF showed that compared with control groups (2800 mg/day), the sodium-restricted groups (1800 mg/day) had increased morbidity and mortality.[52] The trials included in this analysis had several limitations. High doses of diuretics were used in conjunction with strict fluid restriction, which could have resulted in intravascular volume depletion and adverse outcomes. Also, many patients were not on optimal doses of GDMT. There is limited evidence to support sodium restriction in the inpatient setting. In one trial, sodium restriction greater than the standard 2000 mg/day in patients hospitalized for HFrEF did not affect clinical stability or decrease length of stay.[53] For these reasons, further randomized trials are needed to elucidate the impact of sodium restriction on outcomes in patients with HF. Because high

sodium intake leads to HTN, LV hypertrophy, and CV disease, the ACC/AHA HF guidelines[1,11] recommend 1.5 g/daily sodium restriction for patients with stages A and B HF. In patients with advanced HF (stages C and D), <3 g/daily is recommended owing to lack of sufficient data to support any specific degree of restriction.

Even though adherence to dietary sodium restriction is considered "a cornerstone of HF disease management," there are many challenges in implementing dietary sodium restriction. Barriers such as lack of knowledge, interference with socialization, limited access to appropriate food selections, and increased taste preference for salty foods all contribute to lack of adherence to a low-sodium diet.[54,55] Although <1 g of sodium chloride (NaCl) is required to meet physiologic needs, the average U.S. diet contains 10 g. Dietary sodium can be reduced to 2 to 4 g of NaCl by eliminating cooking salt. This diet is more palatable and leads to better adherence than is a severely salt-restricted diet.

DIURETICS

Only those points salient to the treatment of HF are included in this chapter. Diuretic use is discussed in Chapter 9, Essential Hypertension, and Chapter 27, Fluid and Electrolyte Disorders.

Diuretics are indicated in patients with HF with congestion (pulmonary and/or peripheral edema). They produce rapid symptomatic relief. Because activation of the RAAS and sympathetic nervous system contributes to the progression of HF, diuretics should be combined with an ACEI and a β-blocker unless contraindications exist.[1]

Initially, the goal of diuretic therapy is symptomatic relief of HF by decreasing excess volume without causing intravascular volume depletion. Once excess volume is removed, therapy is aimed at maintaining sodium balance and preventing the accumulation of new fluid, while avoiding dehydration. The rate at which volume can be removed is limited by its rate of mobilization from the interstitial to the intravascular fluid compartment. If diuresis is too vigorous, intravascular volume depletion, hypotension, and a paradoxical

decrease in CO may result. Diuretic doses are titrated so that urine output increases and weight decreases, generally by 0.5 to 1.0 kg daily.[1]

The effectiveness of diuretics depends on the amount of sodium delivered to their site of action and the patient's renal function.[56,57] Proximal tubular reabsorption of sodium is increased in patients with severe HF when RBF is compromised, rendering thiazide and potassium-sparing diuretics (which act primarily on the distal tubule) minimally effective. Thiazides are believed to lose their effectiveness when creatinine clearance (CrCl) decreases to <30 mL/minute. Metolazone is an exception in that its activity may be preserved in these patients. The loop diuretics (furosemide, bumetanide, and torsemide) are more potent than are thiazides and retain their effectiveness in renal insufficiency. Thus, in most patients with HF, loop diuretics are preferred. In addition to having activity in the ascending limb of the loop of Henle, furosemide has vasodilating properties that decrease renal vascular resistance. The usual recommended doses for the loop diuretics are found in **Table 14-3**.[56]

Table 14-3
Comparison of Loop Diuretics

	Furosemide	Bumetanide	Torsemide
IV dose equivalence	40 mg	1 mg	20 mg
Maximum total daily dose (IV)	600 mg	10 mg	200 mg
Bioavailability (oral)	10%–100% (average 50%)	80%–100%	80%–100%
Metabolism	50% renal	50% hepatic	80% hepatic
Average duration of action	6–8 hours	4–6 hours	6–8 hours
PO to IV conversion	2:1	1:1	1:1

IV, intravenous.

The effectiveness of diuretics depends on active secretion of the drug in the proximal tubule. Slow absorption (even if bioavailability is high) or protein binding impairs tubular delivery and compromises

diuretic response. Once the drug is in the tubule and the threshold for diuresis is met, further drug delivery produces no greater diuresis. Increasing single doses beyond the ceiling dose produces no additional diuretic response; however, improved diuresis may be obtained by giving the drug more frequently.

A combination of diuretics (a loop diuretic and thiazide) is used in patients who are refractory to high-dose loop diuretics.[56,57] Despite their effects on reducing HF symptoms, loop diuretics do not counteract the underlying cause of HF or modify mortality rates.

ALDOSTERONE ANTAGONISTS

The AAs eplerenone and spironolactone exert a mild diuretic effect by competitive binding to the aldosterone receptor site in the distal convoluted renal tubules. The *R*andomized *AL*dactone *E*valuation *S*tudy (RALES) investigators found that spironolactone reduced both morbidity and mortality in patients in NYHA classes III and IV.[58] The authors speculated that the beneficial effect of spironolactone was related to a reduction in aldosterone-induced vascular damage and myocardial or vascular fibrosis rather than in its diuretic effect. Similarly, reduced mortality and morbidity were observed in patients with LV dysfunction and NYHA class II symptoms with eplerenone.[59] The ACC/AHA HF guidelines[1,11] and the 2021 ACC expert consensus decision pathway for optimization of HF recommend the addition of an AA in all patients with HFrEF who are already on ACEIs or ARB/ARNI and β-blockers irrespective of the severity of symptoms and in patients immediately after MI who have LV dysfunction or diabetes. According to the updated HF guidelines,[2] AAs can be also considered in HFpEF and HFmrEF to reduce hospitalizations and CV mortality.

ANGIOTENSIN CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

Drugs with vasodilating properties are a primary treatment for HF. Arterial dilation provides symptomatic relief of HF by decreasing arterial impedance (afterload). Venous dilation decreases LV

congestion (preload). The combination of these two properties provides additive benefits to alleviate the symptoms of HF and increase exercise tolerance. The first vasodilator drugs to be studied were hydralazine (an arterial dilator) and nitrates (predominately venous dilators). By combining these two drugs, significant reductions in HF symptoms can be achieved along with a reduction in mortality rates. With the advent of ACEIs, the use of hydralazine and nitrates has been relegated to a secondary role and mainly in patients who are African American.

ACEIs possess both afterload- and preload-reducing properties and volume-reducing potential. They produce hemodynamic effects similar to that of the hydralazine–nitrate combination as a single agent, favorably modify cardiac remodeling, have a more tolerable side effect profile, and were superior to hydralazine/ISDN in the **V**asodilator-**H**eart **F**ailure **T**rial **II** (V-HeFT 2) trial (A Comparison of Enalapril with Hydralazine– Isosorbide Dinitrate in the Treatment of Chronic Congestive Heart Failure). These advantages led to the recommendations that ACEIs are the drugs of choice for initial therapy, even in patients with relatively mild LVSD.[1]

The ACC/AHA guidelines[1,11] state that ACEIs should be prescribed to all patients with HFrEF unless they have a contradiction to their use or are unable to tolerate these drugs. In general, ACEIs are used with β-blockers. ACEIs should be initiated at low doses and titrated to maximum doses if well tolerated. Fluid retention can blunt the therapeutic effects, and volume depletion can potentiate the adverse effects of ACEIs. Clinicians should attempt to use doses that have been shown to reduce CV events in clinical trials, but they should not delay the initiation of β-blockers in patients because of a failure to reach clinical trial ACEI doses.[1]

The pharmacologic actions of all the ACEIs are essentially identical, but some of them have not been studied or received FDA approval for use in HF (**Table 14-4**). Their value in HFpEF still is unclear based on neutral trial findings in this population. A related class of drugs is the ARBs.[60,61] ARBs offer theoretic advantages compared with ACEIs by being more specific for angiotensin II

blockade (preferentially bind to AT_1 receptors) and having a lower risk of drug-induced cough.

Table 14-4
Signs and Symptoms of Heart Failure

Left Ventricular Failure	Right Ventricular Failure[a]
Subjective	
DOE	
SOB	
Orthopnea (2–3 pillows)	
PND, cough	
Weakness, fatigue, confusion	Peripheral edema
Weakness, fatigue	
Objective	
LVH	Weight gain (fluid retention)
↓BP	
EF <40%[b]	Neck vein distension
RALES, S_3 gallop rhythm	Hepatomegaly
Reflex tachycardia	Hepatojugular reflux
↑BUN (poor renal perfusion)	

BP, blood pressure; BUN, blood urea nitrogen; DOE, dyspnea on exertion; EF, ejection fraction; LVH, left ventricular hypertrophy; PND, paroxysmal nocturnal dyspnea; SOB, shortness of breath.

[a]Isolated right-sided failure occurs with long-standing pulmonary disease (cor pulmonale) or after pulmonary hypertension.

[b]Ejection fraction normal in patients with diastolic dysfunction.

ARBs can be used as alternatives to ACEIs in patients who are intolerant (angioedema or cough). Triple combination of an ACEI, ARB, and an aldosterone receptor antagonist is potentially harmful for patients and therefore is listed as a class III (avoid) recommendation in the ACC/AHA guidelines.[1,11] Currently, only candesartan and valsartan are FDA approved for the treatment of

HFrEF. The potential to decrease hospitalizations with ARBs in the HFpEF population has been demonstrated.

ANGIOTENSIN RECEPTOR–NEPRILYSIN INHIBITOR

The NP hormones are responsible for both natriuresis and diuresis and are broken down by the neutral endopeptidase neprilysin. To augment NP, several neprilysin inhibitors (ecadotril, candoxatril) were developed in CV diseases. Disappointingly, the development of these drugs was halted owing to lack of efficacy. The most likely explanation for these findings was that neprilysin inhibition also leads to increased plasma concentrations of angiotensin II, thus counteracting the therapeutic benefits of neprilysin inhibition. The next logical step was to combine neprilysin inhibitor therapy with renin–angiotensin system inhibition, leading to the development of omapatrilat. Unfortunately, side effects such as angioedema led to discontinuation of omapatrilat. Because ARBs have a lower incidence of angioedema, a new combination sacubitril/valsartan, an ARNI, was developed and tested in HF.

A randomized, double-blind trial "*P*rospective comparison of *A*ngiotensin *R*eceptor neprilysin inhibitors with *A*ngiotensin-converting enzyme inhibitors to *D*etermine *I*mpact on *G*lobal *M*ortality and morbidity in *H*eart *F*ailure" (PARADIGM-HF)[62] compared sacubitril/valsartan (400 mg daily) to enalapril (20 mg daily) in patients with an LVEF <35%. This trial showed a 20% reduction in the primary outcome of CV death or HF hospitalization in the sacubitril/valsartan group versus the enalapril group. Based on the results of the PARADIGM-HF trial, sacubitril/valsartan received a class I recommendation in HFrEF.[11] The 2017 ACC/AHA/HFSA update on the 2013 HF guidelines recommend switching chronic symptomatic patients with HFrEF (NYHA class II or III) who tolerate an ACEI or ARB to sacubitril/valsartan, to further reduce morbidity and mortality. The 2021 ESC HF guidelines have a class I, level of evidence A recommendation for ACEIs in patients with HFrEF to reduce morbidity and mortality, but further go on to give a class I, level of evidence B recommendation to sacubitril/valsartan as a

replacement for ACEI in patients with HFrEF to reduce the risk of morbidity and mortality.[3]

Also, according to the 2021 ACC expert consensus decision pathway for patients with newly diagnosed stage C HFrEF, ARNI is preferred over ACEI/ARB for initial treatment.[45] A subgroup analysis of the PARAGON-HF[47,63] (*P*rospective comparison of *AR*NI with *A*RB *G*lobal *O*utcomes in heart failure with preserved ejectio*N* fraction) trial showed a significant reduction in HF hospitalization in subjects with LVEF below the median 57% value in the study. Based on this evidence, the FDA has granted an expanded indication to ARNI in patients with HFpEF with an LVEF at the lower end of the range 45% to 57%. The new HF guidelines[2] now recommend ARNI in patients with HFpEF and HFmrEF.

A-ADRENERGIC BLOCKING AGENTS

Until the mid-1990s, β-blockers were contraindicated in patients with HFrEF. This was based on the belief that sympathomimetic agonists and other positive inotropic drugs were the logical choices to counteract systolic failure and that negative inotropic drugs would exacerbate HF. A better understanding of the pathophysiology of HF led to a rethinking of this logic.[15–20,22] In combination with ACEIs, β-blockers are considered first-line agents in patients with HFrEF. The ACC/AHA guidelines state that β-blockers should be prescribed to all patients with HFrEF unless they have a contraindication to their use or are unable to tolerate the treatment. Intolerance or resistance to other HF therapies should not preclude or delay the initiation of β-blocker use in patients with HFrEF.[1] Although some patients can have a temporary worsening of symptoms, continued use results in improved quality of life, fewer hospitalizations, and, most importantly, a reduction in mortality by ~34% when added to other HF therapies. Extended-release (XL) metoprolol succinate, carvedilol, and bisoprolol are FDA approved for use in HFrEF. Metoprolol and bisoprolol are both partially selective β_1-blockers, and carvedilol is a mixed α_1- and nonselective β-blocking agent. Metoprolol can lose β_1-selectivity at higher doses.

IVABRADINE

There is considerable evidence of an association between elevated HRs (>80 beats/minute [bpm]) and increased risk of mortality in patients with HF. The HF trials with β-blockers demonstrated increased mortality with elevated baseline resting heart rates (RHRs) >90 bpm.[64,65] Post hoc analysis of the *C*andesartan in *H*eart failure *A*ssessment of *R*eduction in *M*orbidity and mortality (CHARM)[66] showed that increased RHR was an independent predictor of mortality regardless of LV function or use of β-blockers. A subsequent meta-analysis of HF trials[67] showed an association between the magnitude of HR reduction and survival benefit.

Ivabradine is a selective I_f ("funny current") inhibitor that lowers HR by acting on the sinoatrial node. In 2010, the *S*ystolic *H*eart failure treatment with the I_f inhibitor ivabradine *T*rial (SHIFT)[68] provided evidence for the benefit of HR lowering in patients with HFrEF. Compared to placebo, ivabradine significantly reduced the risk of hospitalization for worsening HF and death due to HF but did not have a significant effect on all-cause mortality.

In April 2015, the FDA approved ivabradine (Corlanor®) for symptomatic chronic HF with LVEF ≤35%, to reduce the risk of hospitalization for worsening HF in adults. The 2017 ACC/AHA/HFSA update on 2013 HF guidelines notes that ivabradine can be beneficial to reduce HF hospitalization for patients with symptomatic (NYHA classes II–III) stable chronic HFrEF (≤35%) who are receiving maximal GDMT, including a β-blocker at maximum tolerated dose, and in sinus rhythm with an HR ≥70 bpm at rest. It received a class IIa recommendation, level of evidence B to R.[11]

DIGITALIS GLYCOSIDES (DIGOXIN)

Digoxin has several pharmacologic actions on the heart. It binds to and inhibits sodium–potassium (Na^+/K^+) adenosine triphosphatase (ATPase) in cardiac cells, decreasing outward transport of sodium and increasing intracellular concentrations of calcium within the cells. Calcium binding to the sarcoplasmic reticulum causes an increase in the contractile state of the heart.

At one time, the primary benefit of digoxin in HFrEF was assumed to be an increase in the force of contraction (positive inotropic effect). We now know that digoxin has beneficial neurohumoral and autonomic effects caused by reducing sympathetic tone and stimulating parasympathetic responses at serum concentrations below those associated with positive inotropism.[69,70] Inhibition of Na^+/K^+ ATPase in vagal afferent fibers sensitizes cardiac baroreceptors, resulting in reduced sympathetic outflow from the CNS. Similarly, inhibition of Na^+/K^+ ATPase in renal cells reduces renal tubular reabsorption of sodium and indirectly suppresses renin secretion. This has led to the suggestion that the positive benefits of digoxin can be obtained using small doses.

Digoxin decreases the conduction velocity and prolongs the refractory period of the atrioventricular (AV) node. This AV node–blocking effect prolongs the PR interval and is the basis for use of digoxin in slowing the ventricular response rate in patients with AF and other supraventricular arrhythmias (see Chapter 15, Cardiac Arrhythmias).

Several studies have confirmed a clinical benefit for digoxin in reducing HF symptoms, independent of rhythm status, but there are no data that demonstrate a beneficial effect on survival. Digoxin is used for symptom management in patients optimally treated with ACEIs, β-blockers, and AAs. In symptomatic patients in stage C or stage D, digoxin can reduce HF-related hospitalizations.[2] Digoxin can be considered in patients with HF who also have AF, although β-blockers are more effective than is digoxin in controlling the ventricular response, especially during exercise.

OTHER VASODILATING DRUGS: HYDRALAZINE AND NITRATES

Although ACEIs are drugs of choice, the first vasodilators evaluated in HFrEF were hydralazine and nitrates. Hydralazine provides symptomatic relief of HF by decreasing afterload. Nitrates have venous dilating properties that decrease preload. Used in combination, these two agents have additive benefits in alleviating the symptoms of HF and increasing exercise tolerance. Importantly,

the hydralazine–isosorbide dinitrate combination was the first treatment regimen to show improved survival in severe HF compared with placebo[70] (while patients continued their diuretic or digitalis therapy). The African American Heart Failure Trial (AHeFT)[71] showed that the addition of hydralazine combined with isosorbide dinitrate to standard HF therapy with an ACEI or a β-blocker improved survival and reduced HF hospitalizations. Based on the results of AHeFT, the FDA approved the combination product of hydralazine and isosorbide dinitrate (BiDil®) for the treatment of HFrEF as an adjunct to standard HF therapy in African American or self-identified Black patients. The combination of hydralazine and nitrate is reasonable in patients with current or prior HF symptoms and reduced LVEF who cannot tolerate ACEIs or ARBs, and is also recommended for patients self-described as Black or African American with moderate-to-severe symptoms on optimal therapy with ACEIs, β-blockers, and diuretics.[2] IV nitroglycerin (NTG) and nitroprusside (a mixed arterial and venous dilator) are also used in hospitalized patients with acute HF exacerbations. The role of these vasodilators in HFpEF is not well studied.

OTHER INOTROPIC AGENTS

IV dopamine and dobutamine, which are sympathomimetics, and milrinone (a phosphodiesterase [PDE] inhibitor) are used in ADHF (see Chapter 17, Shock). They are associated with an increased incidence of mortality but frequently used short term for ADHF. Both dobutamine and milrinone are used chronically in some stage D patients.

Initial positive hemodynamic effects during the first few weeks to months of therapy are followed by increased mortality with continued therapy when compared with placebo. This is related to proarrhythmic effects. Inotropic drugs are contraindicated in HFpEF.

CALCIUM CHANNEL BLOCKERS

Amlodipine, felodipine, isradipine, nifedipine, and nicardipine are examples of dihydropyridine calcium channel blockers (CCBs) with

arterial vasodilating effects. Compared with the non-dihydropyridine CCBs (verapamil and diltiazem), they have minimal negative inotropic properties. Only amlodipine[72] and felodipine[73] have been documented to be safe in HF, but only a small subset of patients with nonischemic dilated cardiomyopathy actually had a beneficial effect of improved survival with amlodipine.[72] Verapamil and diltiazem are safe to use in HFpEF and may improve symptoms by reducing HR and allowing more time to fill the ventricle, but should be avoided in patients with HFrEF because of their negative inotropic effects.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

Ventricular arrhythmias are common in patients with HF ranging from asymptomatic ventricular premature beats to sustained ventricular tachycardia, ventricular fibrillation, and sudden cardiac death (SCD). SCD is highest in patients with severe HF symptoms, or stage D HF.[2] Patients with previous cardiac arrest or documented sustained ventricular arrhythmias have a higher risk of future events. An implantable cardioverter-defibrillator (ICD) is indicated for secondary prevention of SCD in patients with HF who have good clinical function and prognosis, a low EF, and experience syncope of unknown origin, as well as in a small subset of patients with HF who are awaiting a planned cardiac transplant. The ACC/AHA guidelines[2] also recommend ICD for primary prevention of SCD in patients with nonischemic dilated cardiomyopathy or ischemic heart disease at least 40 days after MI, EF of ≤35% despite optimal drug therapy, with mild-to-moderate symptoms of HF, and in whom survival with good functional capacity is otherwise anticipated to extend beyond 1 year (see Case 14-6, Question 4, for a detailed discussion).

CARDIAC RESYNCHRONIZATION

Cardiac resynchronization therapy (CRT) is a therapeutic approach for treating patients with ventricular dyssynchrony (defined as a QRS duration of at least 120 ms). Selected patients with HF benefit from simultaneous pacing of both ventricles (biventricular pacing), or of one ventricle in patients with bundle branch block. The rationale for

using CRT is that dyssynchrony causes ventricular remodeling and worsens HF. CRT can be used alone or with an ICD device. Several clinical trials with CRT or CRT-D[74–77] (cardiac resynchronization defibrillator therapy) have demonstrated improvements in HF functional status, survival, and reduction in hospitalizations. The approved indication for CRT-D includes patients with NYHA class II or ischemic class I HF, with an EF of <30% and a QRS duration of >130 ms, and left bundle branch block (LBBB). These indications are based on results[75] that showed a significant reduction in HF events among patients with mild HF symptoms with CRT-D compared with ICD alone. Current guidelines[1] support the use of CRT in patients with NYHA classes II, III, or ambulatory IV symptoms on GDMT, LVEF of ≤35%, and LBBB with a QRS ≥150 ms (see Case 14-7, Questions 1 and 2).

LEFT VENTRICULAR ASSIST DEVICES

A left ventricular assist device (LVAD) is a battery-operated, mechanical pump that is surgically implanted to maintain the pumping ability of the heart. Clinical trials using LVADs have shown improvement in survival and quality of life. For patients with end-stage HF, LVADs are used as a bridge to transplant or as destination therapy, which is permanent device implantation for patients who are not candidates for a transplant.

The landmark trial REMATCH[78] (*R*andomized *E*valuation of *M*echanical *A*ssistance for the *T*reatment of *C*ongestive *H*eart failure) found that patients with end-stage HF who received an LVAD (HeartMate® XVE) had a 52.1% chance of surviving 1 year, compared with a 24.7% survival rate for patients who received optimal medical therapy. At 2 years, the survival was 23% for the patients with LVAD versus 8% for those receiving medical therapies. However, these survival rates were much lower than those seen with transplantation. Advances in technology led to the introduction of the second-generation devices, notably HeartMate® II, which was approved as a bridge to transplant in 2008.[79] In January 2010, the HeartMate® II (continuous flow), a smaller device, was approved for

destination therapy. In a head-to-head comparison with the first-generation HeartMate® XVE (pulsatile flow), 1- and 2-year survival rates were 68% and 58% with HeartMate® II versus 55% and 24% with HeartMate® XVE.[80] Adverse events were less frequent with the continuous-flow device and patients reported significant improvements in their quality of life. The novel pump called HeartWare ventricular assist device (HVAD®) was tested in patients awaiting cardiac transplantation with refractory and advanced HF.[81] There were less bleeding and fewer infections reported with HVAD; however, the incidence of stroke was higher. This LVAD was removed from the market in 2020 owing to increased neurologic adverse events and mortality compared with similar mechanical circulatory support (MCS) devices.

Patients on continuous-flow LVADs were still susceptible to hemocompatibility-related complications such as pump thrombosis, stroke, and bleeding, despite an improved survival and quality of life. In the largest LVAD study, the centrifugal flow HeartMate® 3 was compared to the axial flow HeartMate® II (HMII). The Multicenter Study of MagLev Technology in Patients Undergoing Mechanical Circulatory Support Therapy with HeartMate 3 (MOMENTUM 3)trial[82] randomized 366 patients with advanced HF requiring LVAD for either bridge or destination therapy (LVEF ≤25%, NYHA III–IV, inotropic dependent or confidence interval [CI] <2.2), HeartMate® 3 centrifugal flow device, or standard-of-care axial flow LVAD (HMII). At 2 years, the HeartMate® 3 device was associated with a 19.3% absolute reduction in reoperation for device malfunction or disabling stroke. Pump replacement at 2 years occurred in 2.3% of patients who received a centrifugal flow pump and in 11.3% of patients receiving HMII. Rates of disabling stroke and death were similar in both groups, although there was a significant reduction in overall stroke ($P < .0001$). The number needed to treat (NNT) over 2 years to avert at least one hemocompatibility-related adverse event (pump thrombosis, stroke, or bleed) was <1. This trial demonstrated superior performance of the HeartMate® 3 compared to the axial flow HeartMate® II pump with respect to the following: absolute reduction in pump thrombosis rates, reduction in strokes of any type and of

any severity, and reduction in any bleeding, particularly gastrointestinal bleeds. HeartMate® 3 received FDA approval in 2017. Devise-related complications continue to be a challenge, and, for now, in patients ineligible for heart transplantation, the field of LVAD continues to grow.

NEW THERAPIES IN HEART FAILURE WITH REDUCED EJECTION FRACTION

Vericiguat

Patients with HF often present with endothelial dysfunction resulting in decreased production of nitric oxide (NO). NO stimulates soluble guanylate cyclase (sGC) and increases the production of cyclic guanosine monophosphate (cGMP), causing vasodilation of vascular smooth muscles. Similarly, endocardial endothelium via NO regulates contractility and diastolic dysfunction; hence, any deficiency in the NO-SGc-CGMP pathway can impair diastolic relaxation and microvascular dysfunction.[83] Furthermore, experimental studies have suggested that sGC stimulators can reverse left ventricular hypertrophy (LVH) and fibrosis. Hence, pharmacologic agents that help restore the (NO)-sGC–cGMP signaling pathway have been recently developed in the treatment and prevention of HF.

Unlike the nitrates, vericiguat directly binds sGC increasing the CGMP production, which, in turn, enhances endogenous availability of NO, leading to favorable downstream effects on the CV system. Vericiguat in Patients with Heart Failure and Reduced Ejection Fraction (VICTORIA Study Group)[84] was a randomized double-blind placebo-controlled multinational study that included 5050 patients with LVEF <45%, NYHA classes II to IV HFrEF, elevated NP level in the 30 days before randomization (sinus rhythm: BNP ≥300 pg/mL or NT-proBNP ≥1000 pg/mL, AF: BNP ≥500 pg/mL or NT-proBNP ≥1600 pg/mL), and evidence of worsening HF (HF hospitalization within 6 months of randomization, or IV diuretic therapy without hospitalization in the past 3 months). Patients received vericiguat 10 mg daily versus placebo and were on excellent background therapy

with >90% on β-blockers and an ACEI, ARB, or ARNI. More than 40% of the patients had stage 3 chronic kidney disease. The primary outcome was a composite of death from CV causes or first hospitalization for heart failure. Over 10.8 months, 897 of 2526 patients (35.5%) in the vericiguat group experienced a primary outcome event, compared with 972 of 2524 patients (38.5%) in the placebo group, for a hazard ratio (HR) of 0.90, 95% CI, 0.82 to 0.98; *P* = .02. The main finding was the reduction in hospitalizations that drove the primary composite end point (HR 0.90, 95% CI 0.81–1, *P* = .048, absolute risk reduction [ARR] 2.2%, NNT 46). Generally, the drug was very well tolerated. Symptomatic hypotension occurred in 9.1% of the patients in the vericiguat group and in 7.9% of the patients in the placebo group (*P* = .12); syncope occurred in 4.0% of the patients in the vericiguat group and in 3.5% of the patients in the placebo group (*P* = .30). VICTORIA enrolled a very high-risk population with HF having significant unmet needs not well addressed by prior HF studies. Given the positive results of this trial, vericiguat will likely be added to the guidelines, particularly for high-risk patients who carry the residual risk of CV death despite receiving optimal GDMT, with a high event rate as seen in the trial. Because vericiguat is a once-daily medicine, easy to titrate, generally safe and well tolerated, without the need for monitoring renal function or electrolytes, it may play a useful role in patients with a recent worsening HF. According to the ESC and AHA/ACC/HFSA guidelines,[2,3] vericiguat may be considered, in addition to standard therapy for HFrEF, to reduce the risk of CV mortality and hospitalizations for HF.

Sodium–glucose cotransporter-2 (SGLT2) inhibitors

Despite the many medications that have demonstrated benefits in lowering the risk of morbidity and mortality in patients with HFrEF, there remains a need to continue to further lower this risk. SGLT2 inhibitors have been utilized to help improve glycemic control in patients with type 2 diabetes mellitus, but recently have demonstrated benefit in patients with or without diabetes. There are

a number of proposed mechanisms for this benefit, which include improvement in ventricular loading by reducing preload and afterload, providing an alternative cardiac energy supply in the form of cardiac ketones, direct inhibition of sodium/hydrogen exchange in the myocardium leading to reductions in cardiac injury, reduction in LV mass, improvement in endothelial function, and stimulation of increased glucagon secretion potentially improving cardiac performance.[47] The exact mechanism of benefit has yet to be fully determined at this point.

The two SGLT2 inhibitors that have demonstrated benefit in the population with HFrEF to reduce CV death and HF hospitalization are dapagliflozin and empagliflozin. The two clinical trials were the *D*apagliflozin *A*nd *P*revention of *A*dverse outcomes in *H*eart *F*ailure (DAPA-HF)[85] and *EMP*agliflozin outcomE t*R*ial in patients with chr*O*nic hea*R*t failure and a *R*educed ejection fraction (EMPEROR-Reduced).[86] DAPA-HF was a clinical trial of NYHA classes II to IV HF with an EF <40% who were randomized to dapagliflozin 10 mg or placebo daily. The primary outcome was a composite of worsening HF (hospitalization or an urgent visit resulting in IV therapy for HF) or CV death. The study lasted a median of 18.2 months. The primary outcome occurred in 16.3% of the dapagliflozin group and in 21.2% of the placebo group (HR, 0.74; 95% CI, 0.65–0.85; $P < .001$). All individual components of the primary outcome were statistically significant as well. Based on this trial, the FDA approved dapagliflozin for the treatment of HFrEF in adults with or without diabetes in May 2020. The EMPEROR-Reduced trial was a clinical trial of NYHA classes II to IV HF with an EF <40% who were randomized to empagliflozin 10 mg or placebo daily. The primary outcome was a composite of CV death or hospitalization for worsening HF. The study lasted for a median of 16 months. The primary outcome event occurred in 19.4% of the empagliflozin group and 24.7% of the placebo group (HR, 0.75; 95% CI, 0.65–0.86; $P < .001$). Hospitalization for HF was statistically significant as an individual end point, but CV death did not reach significance as an individual outcome. Based on the findings of these studies, SGLT2 inhibitors (dapagliflozin, empagliflozin) have a class I

recommendation inhibitor for HFrEF with NYHA classes II to IV patients to reduce the risk of HF hospitalization and death. The 2022 HF guidelines[2] recommend SGLT2 inhibitors for HFpEF and HFmrEF to decrease HF hospitalizations and CV mortality. This expanded indication is based on the results of Empagliflozin Outcome Trial in Patients with Chronic Heart Failure with Preserved Ejection Fraction (EMPEROR-Preserved).[48]

PATIENT EVALUATION

Signs and Symptoms

CASE 14-1

Question 1: A.J., a 58-year-old male, is admitted with increasing SOB and a 17.64-pound (8-kg) weight gain. Two weeks before admission, he noted the onset of dyspnea on exertion (DOE) after one flight of stairs, orthopnea, and ankle edema. Since then, his symptoms have worsened. He has also noted episodic bouts of paroxysmal nocturnal dyspnea (PND), and he has been able to sleep only in a sitting position. A.J. reports a productive cough, nocturia (two to three times a night), and edema.

A.J.'s other medical problems include a long history of heartburn, a 10-year history of osteoarthritis, depression, and poorly controlled HTN. A family history of diabetes mellitus is also present.

Physical examination reveals dyspnea, cyanosis, and tachycardia. A.J. has the following vital signs: BP, 160/100 mm Hg; pulse, 90 bpm; and respiratory rate, 28 breaths/minute. He is 71 inches (180.34 cm) tall and weighs 171.96 pounds (78 kg). His neck veins are distended. On cardiac examination, an S_3 gallop is heard; the point of maximal impulse is at the sixth intercostal space, 12 cm from the midsternal line. His liver is enlarged and tender to palpation, and a positive hepatojugular reflux is observed. He is noted to have 3+ pitting edema of the extremities and sacral edema. Chest examination reveals inspiratory rales and rhonchi bilaterally.

The medication history reveals the following current medications: hydrochlorothiazide (HCTZ) 25 mg every day, ibuprofen 600 mg four times a day (qid), ranitidine 150 mg every night at bedtime, and citalopram 20 mg every day. He has no allergies and no dietary restrictions.

Admitting laboratory values include the following:

Hematocrit, 41.1%
White blood cell count, 5300/μL
Sodium (Na^+), 132 mEq/L
Potassium (K^+), 3.2 mEq/L
Chloride (Cl^-), 100 mEq/L
Bicarbonate, 30 mEq/L
Magnesium, 1.5 mEq/L
Fasting blood sugar, 100 mg/dL
Uric acid, 8 mg/dL
Blood urea nitrogen (BUN), 40 mg/dL
Serum creatinine (SCr), 0.8 mg/dL
Alkaline phosphatase, 44 units/L
Aspartate aminotransferase, 30 units/L
BNP, 1364 pg/mL (normal <100 pg/mL)
Thyroid-stimulating hormone, 2.0 μU/mL

The chest radiograph shows bilateral pleural effusions and cardiomegaly.

What signs, symptoms, and laboratory abnormalities of HF does A.J. exhibit? How do you relate these clinical findings to the pathogenesis of the disease and to left-sided or right-sided HF?

Left-sided ventricular dysfunction primarily causes pulmonary symptoms, whereas right-sided ventricular dysfunction causes signs of systemic venous congestion. Although LV failure usually develops first, many patients present with signs of biventricular failure. The signs and symptoms of both left-sided and right-sided ventricular dysfunction are summarized in **Table 14-4**.

LEFT-SIDED HEART FAILURE (LEFT VENTRICULAR DYSFUNCTION)

Weakness, fatigue, and cyanosis result from decreased CO and compromised tissue perfusion. If the left ventricle is not emptied completely, pulmonary congestion occurs. Dyspnea (labored or uncomfortable breathing) on exertion, a productive cough, rales (crackles in the lung during auscultation), pleural effusions on chest radiograph, and hypoxemia all result from pulmonary congestion. Pulmonary symptoms are aggravated in the reclining position. Orthopnea or SOB in the supine position is quantified by the number of pillows the patient must lie on to sleep comfortably. A.J., for

example, could sleep only sitting upright. PND is characterized by SOB that awakens the patient from sleep and is alleviated by an upright position.

Cardiac dilatation is observed on chest radiography as an enlarged cardiac silhouette. The point of maximal impulse corresponds to the apex of the left ventricle and is visualized as an external pulsation on the left side of the chest. It is displaced laterally and downward from its normal location at the fifth intercostal space, <10 cm from the midsternal line. An S_3 gallop rhythm denotes a third heart sound often heard in close proximity to the second heart sound (closing of the aortic and pulmonary valves) in HF. Rapid filling of the ventricles causes the S_3 sound and, in an adult, usually indicates decreased ventricular compliance. In patients with mitral valve regurgitation, an S_3 heart sound is common and denotes systolic dysfunction and elevated filling pressure. Tachycardia is caused by compensatory increases in sympathetic tone.

Weight gain and edema reflect sodium and water retention resulting from decreased renal perfusion (see the section on Pathogenesis). As RBF and GFR decrease, a disproportionate amount of BUN may be retained. This phenomenon is termed *prerenal azotemia* and is detected by an elevated BUN-to-SCr ratio of >20:1. A.J. has a ratio of >40:1. Prerenal azotemia also can be caused by dehydration and overuse of diuretics. Frequency of urination at night (nocturia) is caused by improved perfusion of the kidney when the patient is lying down.

RIGHT-SIDED HEART FAILURE (RIGHT VENTRICULAR DYSFUNCTION)

The signs and symptoms of right ventricular dysfunction are related to hypervolemia, valvular disease, or pulmonary HTN. The overall effect is elevation in central venous pressure.

Dependent edema results from increased venous and capillary hydrostatic pressure, causing a redistribution of fluid from the intravascular to interstitial spaces. Ankle and pretibial edema are common findings after prolonged standing or sitting because fluid

tends to localize in the dependent portions of the body secondary to gravitational forces. Sacral edema can be present in patients at bed rest. Edema is subjectively quantified on a 1+ (minimal) to 4+ (severe) scale. A.J. has 3+ pitting edema.

Hepatomegaly, hepatic tenderness, and ascites (fluid in the abdomen) arise from hepatic venous congestion and increased portal vein pressure. Metabolism of drugs highly dependent on the liver for elimination can be impaired by both the retrograde venous congestion of the liver from right-sided HF and the decreased arterial perfusion of the liver from left-sided HF. Congestion of the gastrointestinal tract makes the patient anorectic.

Neck vein distension, primarily seen as internal jugular venous distension, denotes an elevated jugular venous pressure (JVP).

How high the neck veins are distended while the patient is lying down and how much the patient's head has to be raised before the jugular venous distension disappears gives the clinician a rough estimate of the patient's central venous pressure. Jugular distension in centimeters is measured as the vertical distance from the top of the venous pulsation down to the sternal angle. Neck vein distension of <4 cm when the patient is lying with the head elevated at a 45-degree angle is considered normal for an average, healthy adult. Applying pressure to the liver can cause further distension of the neck veins if hepatic venous congestion is present. This phenomenon is termed *hepatojugular reflux.*

EJECTION FRACTION MEASUREMENT

CASE 14-1, QUESTION 2: Does A.J. have LVSD?

SOB, crackles on auscultation, neck vein distension, edema, and nearly all of A.J.'s other signs and symptoms provide some important clues about the nature of the underlying cardiac abnormalities; however, they are limited in evaluating structural abnormalities. Some of these symptoms can be confused with other disorders, especially reduced exercise intolerance, which is often a gradual

process that patients may fail to recognize and report. An enlarged heart on a chest radiograph increases the suspicion of LVSD, but this finding can be absent in some patients with LVSD and present in others with normal LV function. Some patients may be asymptomatic with structural abnormalities.

The most useful method to diagnose HF with LVSD is by measuring the LVEF. All patients with suspected HF should have an EF measured before beginning therapy because the treatment strategies between HFrEF and HFpEF differ. Two-dimensional echocardiography coupled with Doppler flow studies (Doppler echocardiogram) is the diagnostic test of choice for measuring EF. This procedure uses sound waves to visualize and measure ventricular wall thickness, chamber size, valvular function, and pericardial thickness. EF is estimated based on changes in ventricular chamber size between diastole and systole. This method of EF measurement is not as technically accurate as that provided by ventriculography, but the procedure is more comfortable for the patient and the correlation of the measured EF to that of the other methods is acceptable.

Radionuclide left ventriculography (also called a multiple gated acquisition scan) uses radiolabeled technetium as a tracer to measure LV hemodynamics. Although this method is the most accurate measurement of EF, it is moderately invasive because it requires venipuncture and radiation exposure. In addition, radionuclide scanning does not provide information on the architecture of the left ventricle. Magnetic resonance imaging and computed tomography are useful in evaluating ventricular mass but do not provide EF data.

Subsequently, A.J. underwent an echocardiogram. The results were reported as LVH with mild-to-moderate depression of EF (30%–40%). Because he has systolic dysfunction and classic congestive signs, he fits the criteria for having congestive HF.

STAGES OF HEART FAILURE AND NEW YORK HEART ASSOCIATION CLASSIFICATION

Case 14-1, Question 3: What stage of HF does A.J. exhibit according to the ACC/AHA criteria? How severe is A.J.'s disability, according to the NYHA functional classification of HF?

The updated ACC/AHA staging scheme and the NYHA functional classification are summarized in **Figure 14-5**.[4,28]

PREDISPOSING FACTORS

Case 14-1, Question 4: What factors contributed to the cause of A.J.'s HF?

Age, HTN, MI, diabetes, tachycardia-induced cardiomyopathy, valvular heart disease, and obesity are well-established major risk factors associated with the development of HF. Other risk factors associated with HF are smoking, excessive intake of alcohol, dyslipidemia, anemia, and chronic kidney disease.[87] There is interest in biochemical and genetic markers that are associated with HF. CAD, and MI, in particular, is considered to be the most significant risk factor for HF in the elderly. During the past decades, there has been an increase in the incidence of HF after MI owing to the increased survival after MI.[88]

A.J. is especially vulnerable to HF because of his poorly controlled HTN, which increases afterload. HTN can lead to LVH, which is a compensatory response to increased afterload. LVH is associated with a higher risk of HF, especially in younger individuals.[6] The lifetime risk for individuals developing HF with BP of at least 160/90 mm Hg is double that for those with BP <140/80 mm Hg.[89] Preventive strategies directed toward earlier and more aggressive BP control can reduce the incidence of HF by almost 50% and its associated mortality as well.[6]

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS AND SODIUM CONTENT

Nonsteroidal anti-inflammatory drugs (NSAIDs) exert their anti-inflammatory effects by inhibiting prostaglandins. Blocking

prostaglandins leads to sodium reabsorption and counteracts the beneficial effects of diuretics and ACEIs. The ibuprofen used for A.J.'s arthritis contributes to sodium overload. Epidemiologic studies indicate that NSAIDs exacerbate HF symptoms, resulting in hospitalizations for HF.[90–92] ACC/AHA practice guidelines recommend avoiding NSAIDs whenever possible in patients with HF.[1]

Another potential source of excess sodium is in IV formulations. Sodium chloride is often used as a diluent for IV drug administration. Some parenteral antibiotics, particularly nafcillin and ticarcillin, have high sodium content. Most prescription and nonprescription drug labels carry a disclosure of sodium content.

A.J.'s HTN and HF are both poorly controlled and he has gained 17.64 pounds (8 kg). His clinical presentation (orthopnea, dyspnea, SOB, lower extremity edema, elevated JVP) clearly indicates fluid overload. This could be a result of high-dose ibuprofen use. His HCTZ should be replaced by a loop diuretic to enhance diuresis. Also, an ACEI should be added to the current regimen for BP control. Once he is euvolemic, the addition of a β-blocker before discharge should be considered. Lowering the dose or preferably discontinuing all NSAIDs might reduce sodium retention and allow ACEI therapy to be more effective. Acetaminophen is an alternative for treating his osteoarthritis.

DIET

It is possible that A.J.'s diet contains a considerable excess of sodium from foods such as canned soups and vegetables, potato chips, or overuse of salt at mealtime. Dietary supplements and sports drinks can also be rich sources of sodium. He should follow a controlled-sodium (2–3 g/day) diet. If salt substitutes are used, he should be warned that they are high in potassium and could cause hyperkalemia if used concurrently with potassium supplements, an AA, or other potassium-sparing diuretics.

Drug-Induced Heart Failure

Case 14-1, Question 5: What are the basic mechanisms by which drugs can induce HF, and how can an understanding of these mechanisms be predictive of the drugs to avoid in A.J.?

Drug-induced HF is mediated by three mechanisms: inhibition of myocardial contractility (negative inotropic agents and direct toxins), proarrhythmic effects, or expansion of plasma volume (**Table 14-5**). The latter category includes drugs that act primarily on the kidney (to either alter RBF or increase sodium retention) or those that increase total body sodium and water because of their high sodium content.

Table 14-5
Drugs That May Induce Heart Failure

Negative Inotropic Agents	
β-Blockers[a]	Most evident with propranolol or other nonselective agents
	Less with agents with intrinsic sympathomimetic activity (acebutolol, carteolol, pindolol); can also be caused by use of timolol eye drops
Calcium channel blockers[a]	Verapamil has most negative inotropic and AV-blocking effects; amlodipine has least.
Antiarrhythmics	Disopyramide, flecainide, dronedarone
Direct Cardiotoxins	
Cocaine, amphetamines	Overdoses and long-term myopathy
HER2-Targeted Therapies	Trastuzumab, pertuzumab
Alkylating agents	Cyclophosphamide
Proarrhythmic Effects	
Class IA, class III antiarrhythmic drugs	QT interval widening
	Probable torsades de pointes
	HF develops if disturbed rhythm compromises cardiac functioning.
Nonantiarrhythmic drugs	Same mechanism as given earlier
(See Crouch et al[91] for a	Often associated with drug interactions that inhibit

complete list)	the metabolism of the offending drug, leading to higher than desired plasma levels
Expansion of Plasma Volume	
Antidiabetics	
	Na retention with pioglitazone and rosiglitazone
NSAID	Prostaglandin inhibition; Na retention
Glucocorticoids, androgens, estrogens	Mineralocorticoid effect; Na retention
Licorice	Aldosterone-like effect; Na retention
Antihypertensive vasodilators (hydralazine, methyldopa, prazosin, minoxidil)	↓Renal blood flow, activation of renin–angiotensin system
Drugs high in Na^+	Selected IV cephalosporins and penicillins
	Effervescent or bicarbonate-containing antacids or analgesics
	Also liquid nutrition supplements
Unknown Mechanism	
Tumor necrosis factor antagonists	Multiple case reports of new-onset HF or exacerbation of prior HF with etanercept and infliximab in patients with Crohn disease or rheumatoid arthritis

AV, atrioventricular; HF, heart failure; IV, intravenous; Na, sodium; NSAID, nonsteroidal anti-inflammatory drugs.

[a]β-Blockers and verapamil may be beneficial in diastolic heart failure. Carvedilol and metoprolol counteract autonomic hyperactivity in systolic dysfunction.

Because A.J. has symptoms of HF and structural changes in cardiac architecture, he is in ACA/AHA stage C. On admission, A.J. is in NYHA functional class III as evidenced by a need to sleep upright and an inability to undertake even minimal physical activity. It is important to recognize that HF can progress very slowly in some patients and very rapidly in others. A patient with MI could move from stage A to stage C.

The most recognized negative inotropic agents are the β-blockers, which decrease myocardial contractility and slow the HR. Both of these factors can compromise CO. Other well-documented negative inotropic drugs include the non-dihydropyridine CCBs (verapamil and diltiazem), and some antiarrhythmic agents (disopyramide, flecainide, and dronedarone). The anthracyclines (daunorubicin and doxorubicin) have a direct, dose-related cardiotoxicity that can be minimized by limiting total cumulative doses to 500 mg/m^2 (see Chapter 94, Adverse Effects of Chemotherapy, Immunotherapy, and Targeted Agents).[93,94] Cocaine and alcohol are cardiotoxins when used chronically in large quantities or after an overdose. Drugs that increase the incidence of arrhythmias will worsen HF if the abnormal rhythm compromises cardiac functioning or output.

Drugs that promote sodium and water retention include NSAIDs, certain antihypertensive drugs, glucocorticoids, androgens, estrogens, and licorice. Weight gain and peripheral and pulmonary edema have been observed in patients on pioglitazone and rosiglitazone.[95] Worsening of HF appears to be dose dependent and presumed to be at least partly caused by fluid retention. As a consequence, the package inserts for pioglitazone and rosiglitazone recommend they not be administered to patients with NYHA class III or IV HF and that they be used cautiously in earlier stages of HF.[95] Saxagliptin has been also associated with an increased risk of HF hospitalizations. The FDA has initiated an investigation to further evaluate this risk.[96]

TREATMENT

Therapeutic Objectives

Case 14-1, Question 6: What are the therapeutic goals in treating A.J.?

Cure is not a feasible therapeutic objective in patients with most forms of HF, the exceptions being patients who are candidates for cardiac transplantation or who have certain forms of viral, alcohol-induced, or tachycardia-induced dilated cardiomyopathy. The immediate objective for A.J. is to provide symptomatic relief by reducing his SOB and PND, improve sleep quality, and increase exercise tolerance. Parameters to measure success include reduced peripheral and sacral edema, weight loss, slowing of the HR to <90 bpm, normalization of BP, reduction of BUN, reduction of heart size on chest radiograph, decreased neck vein distension, and loss of the S_3 heart sound. Long-range goals are to improve A.J.'s EF and quality of life including better tolerance of daily life activities, fewer future hospitalizations, avoidance of side effects of his therapy, and, ultimately, an increased survival time. The achievement of these goals depends on the severity of A.J.'s disease, his understanding of his disease, and his adherence to prescribed interventions.

Diuretics

FUROSEMIDE AND OTHER LOOP DIURETICS

Case 14-1, Question 7: Bed rest and a 3-g sodium diet were ordered. The medical team decides to begin furosemide for A.J. What is the rationale for using diuretics and what route, dose, and dosing schedule should be used?

Excessive volume increases the workload of a compromised heart, and diuretics are an integral part of therapy. This is especially true if volume overload is symptomatic (dyspnea) as it is in A.J. Diuretics produce rapid symptomatic improvement. They relieve pulmonary and peripheral edema within hours, whereas the effects of ACEIs, β-blockers, and digoxin take days to months to be fully realized. Diuretics, however, should not be used alone. Even when they are initially successful in controlling symptoms and reducing edema, they are ineffective in maintaining clinical stability for long periods without the addition of other drugs. More importantly,

activation of the RAAS and sympathetic nervous system in response to diuresis could lead to HF progression.

All current guidelines recommend diuretic therapy, both acutely and chronically, if clinical volume overload is evident, but further state that patients without edema can be treated either intermittently or without diuretics.[1] Diuretics used on an intermittent (as-needed) basis are titrated based on changes in weight gain, neck vein distension, peripheral edema, or SOB. Patients with a good understanding of their disease can be instructed to weigh themselves daily and start taking their diuretic if they gain >1 to 2 pounds (0.45–0.90 kg) in 1 day or 5 pounds (2.27 kg) in 1 week or have leg or abdominal swelling. Diuretics can be withheld as long as patients are at their target dry weight. In other cases, diuretic-free intervals or weekends can be arranged. Even with these options, if the patient has experienced volume overload at some time during the course of their disease, either past or present, a diuretic should always be readily available.[97] Despite remarkable initial benefits, vigorous diuretic therapy carries the risk of volume depletion, electrolyte abnormalities, and diminished CO. Abrupt worsening of renal function (increased BUN or SCr) or hypotension indicates the need to temporarily withhold diuretics.

Route of administration

Furosemide is a commonly used loop diuretic because of clinical experience and low cost. Bumetanide and torsemide are preferred in some settings because of more predictable absorption.[47,63,98,99] Ethacrynic acid, which is also a loop diuretic, is not preferred because of its ototoxic potential. However, unlike other loop diuretics, ethacrynic acid does not contain a sulfonamide moiety, and it is mainly reserved for patients with severe sulfonamide allergies to other loop diuretics.

According to one group of investigators, patients with HF treated with torsemide fare better than do those receiving furosemide.[99] During a 1-year open-label trial, patients receiving torsemide were less likely to be admitted to the hospital for HF (17% torsemide vs

32% furosemide). Admissions for all CV causes were also lower among patients taking torsemide (44%) than among patients taking furosemide (59%). Fatigue scores improved to a greater extent in patients treated with torsemide, but no difference was found in the dyspnea score. Torsemide is more expensive than is furosemide, and this may be an issue for some patients.

Erratic responses to furosemide are prevalent in persons with severe HF or diminished renal function. Some patients respond promptly and vigorously to small oral doses of furosemide, whereas others require large IV doses to achieve only minimal diuresis. Part of these differences can be explained by the drug's pharmacokinetics.[56,100] Loop diuretics are highly protein bound and have to be actively secreted into the proximal tubular lumen to elicit a response. Tubular secretion of loop diuretics can be compromised in the presence of increased levels of endogenous organic acids because of renal insufficiency and drugs (NSAIDs) that are competing for the same transporters. Also, oral absorption of furosemide is erratic and incomplete, averaging 50% to 60% in healthy subjects and 45% in those with renal failure. When taken with a meal, absorption is delayed, but the total amount absorbed does not differ. There are claims that the absorption and, therefore, effectiveness of furosemide are further diminished in patients with HF attributable to edema of the bowel and decreased splanchnic blood flow. This has been partially refuted by one investigator, who noted an average furosemide bioavailability of 61% in patients with HF, the same as in normal patients.[99] Total absorption in patients with HF varies widely (34%–80%); however, both the rate of absorption and the time to peak urinary excretion are delayed for furosemide and bumetanide.[56,57,101]

The rate and extent of absorption are not only different among individuals but intraindividual variability also exists. Ingestion of the same brand of furosemide by the same individual on multiple occasions can show up to a threefold difference in bioavailability. These differences are evident with the innovator's brand (Lasix®) or generic brands.[102,103]

Dosing

Typically, a patient's treatment is initiated with 20 to 40 mg of oral or IV furosemide given as a single dose and monitored for responsiveness (see **Table 14-3**). If the desired diuresis is not obtained, the dose can be increased in 40- to 80-mg increments to a total daily dose of 160 to 240 mg, usually divided into two or three doses. For torsemide, a usual starting dose is 10 to 20 mg/day, but a ceiling effect is noted in patients with HF at a dosage of 100 to 200 mg/day.[104] Equivalent doses of bumetanide are 0.5 to 1.0 mg once or twice daily, titrated to a maximum of 10 mg daily. Because A.J. is not in acute distress, it could be argued that oral therapy would suffice. The decision, however, is to give a single 40-mg IV dose of furosemide for immediate symptom control. Further increases in the dose or frequency (ie, twice-daily dosing) of diuretic administration may be required to maintain an active diuresis and sustain weight loss.

Another alternative in hospitalized patients is to administer loop diuretics via continuous infusion. Multiple studies have demonstrated the benefits of continuous infusions compared with intermittent infusions.[105–107] However, the results of these studies have been questioned because of a lack of methodologic rigor, and the studies have been underpowered to address the primary end points. Recently, the DOSE (Diuretic Optimization Strategies Evaluation) trial[108] showed no difference in efficacy or safety between intermittent IV bolus and continuous infusion. There are potential benefits of continuous infusion when compared with intermittent bolus dosing. Bolus diuretic dosing can cause a higher rate of diuretic resistance owing to the postdiuretic phenomenon. Continuous IV infusion results in a constant delivery to the tubule, potentially reducing this phenomenon. In addition, continuous infusions are also associated with a lower incidence of ototoxicity owing to lower peak concentrations. Patients who are candidates for continuous IV infusion should receive a loading dose before infusion to reach steady-state concentrations faster. However, if the patient has received one or more IV boluses within the previous few hours, then

an infusion can be started without a loading dose. In case of inadequate response, the loading dose should be repeated, and the infusion rate increased. The infusion rate depends on the patient's renal function and response.

ADVERSE EFFECTS

CASE 14-1, QUESTION 8: Examine A.J.'s laboratory values (see Question 1). Does A.J. have any abnormal values? What is the significance of these abnormalities?

Azotemia

A.J. has an elevated BUN (40 mg/dL) but a normal SCr (0.8 mg/dL). Worsening renal function is characterized by an elevation of BUN and creatinine. A disproportionately elevated BUN relative to creatinine is indicative of prerenal azotemia, secondary to poor renal perfusion from HF or overdiuresis. SCr will also rise in some patients with prerenal azotemia but will quickly return to normal with rehydration.

A.J.'s laboratory values reflect prerenal azotemia. The most probable cause of his azotemia is decreased RBF secondary to decompensated HF. Diuretics should not be withheld and, in fact, judicious diuresis should improve his HF and help lower his BUN. Caution must be exercised because excessive diuresis and volume depletion can cause renal ischemia, leading to true renal damage. If this happens, the SCr also will rise.

Hyponatremia

A low serum sodium of 132 mEq/L is noted. Low serum sodium, however, is not necessarily a sign of overdiuresis. A person may be significantly overdiuresed with a body deficit of sodium, but if that sodium is lost isotonically, the serum sodium concentration will be normal. Conversely, a person such as A.J. can be hypervolemic, indicating excessive body sodium, but the serum sodium concentration may be normal or even low.

Hyponatremia (low serum sodium concentration) reflects the dilutional effect of extra free water in the plasma. The most common causes of dilutional hyponatremia are excess ADH production or excessive free water intake. Individuals on severely sodium-restricted diets can experience hyponatremia. Likewise, patients given too much diuretic and who are then given salt-free fluids or who have compensatory ADH release can become hyponatremic. Patients with HF or hepatic cirrhosis are more likely to develop diuretic-induced dilutional hyponatremia because of preexisting defects in free water excretion. The exact cause of hyponatremia in A.J. is unknown, but his marginally low serum sodium does not contraindicate continued diuretic therapy. In general, levels of serum sodium concentration <120 to 125 mEq/L are associated with adverse events in patients with HF; chronic serum sodium concentrations of ≤130 mEq/L are associated with higher morbidity and mortality.[109] Asymptomatic hyponatremia can be treated with water restriction. In the setting of volume depletion, IV administration of normal saline may be effective. Vasopressin receptor antagonists can be used in patients with HF and hypervolemic hyponatremia.

Hypokalemia

A.J. has a serum potassium of 3.2 mEq/L. Hypokalemia is associated with an increased incidence of arrhythmias. Some studies showed increased ectopic activity with serum levels between 3.0 and 3.5 mEq/L.[110–112] It is estimated that the risk of arrhythmias increases by 27% with each 0.5 mEq/L reduction in the plasma potassium concentration <3.0 mEq/L.[113]

In chronic HF, potassium abnormalities are commonly seen. The risk of SCD in patients with HF may be lessened by using low doses of diuretics in combination with potassium-sparing agents, with the goal of maintaining serum potassium levels between 4.5 and 5.0 mEq/L.[114]

A.J. will be receiving increased doses of diuretics for the next several days and, therefore, may need additional potassium supplementation to prevent life-threatening hypokalemia. In addition,

if he needs digoxin therapy in the future, low serum potassium levels can predispose him to digitalis toxicity. Potassium replacement is warranted for A.J. at this time. Long-term potassium supplementation may not be necessary with concomitant administration of ACEIs. If hypokalemia persists, A.J. can be started on an AA.

Hypomagnesemia

A.J.'s serum magnesium level is 1.5 mEq/L. Severe hypomagnesemia can lead to somnolence, muscle spasms, a decreased seizure threshold, and cardiac arrhythmias, effects similar to those seen with hypokalemia. Some investigators have claimed that many of the arrhythmias previously ascribed to diuretic-induced hypokalemia were actually caused by diuretic-induced hypomagnesemia.[115] Concurrent hypokalemia and hypomagnesemia can be especially dangerous. A.J. should be given 1 g of magnesium sulfate IV and observed for changes in his magnesium level. If needed, he could be given chronic oral supplements of magnesium.

Hyperuricemia

Increases of 1 to 2 mg/dL in uric acid levels are common during thiazide administration. Rarely, 4- to 5-mg/dL elevations have been reported. A.J.'s uric acid level is 8 mg/dL, which is slightly elevated. It has been proposed that serum uric acid levels may be a valuable prognostic marker in patients with HF. One study indicates a graded relationship between serum uric acid and HF survival.[116] In HF, xanthine oxidase is upregulated, which can lead to endothelial dysfunction. Therefore, treatment with allopurinol may improve endothelial function and promote reverse remodeling. The relationship between serum uric acid and CV disease is still controversial, and the guidelines do not recommend the use of xanthine oxidase inhibitors to prevent CV disease. In patients who experience symptomatic hyperuricemia, the addition of allopurinol or other urate-lowering agents should be considered (see Chapter 45, Gout and Hyperuricemia).

B-type natriuretic peptide

A.J.'s BNP is elevated (1365 pg/mL). Various studies evaluating the diagnostic accuracy of BNP and NT-proBNP have used different lower limits to define normal values. The most commonly used plasma concentration to define the upper limit of normal for BNP is 100 pg/mL, with concentrations >400 pg/mL being considered a strong indicator of HF. The age-related NT-proBNP diagnostic upper limit of normal is 125 pg/mL for patients younger than age 75 years, and 450 pg/mL for patients older than age 75 years. If the patient has a level below the upper limit of normal for the respective assay used, then the symptoms are most likely attributable to causes other than HF. In patients with renal impairment, the clearance of these peptides is reduced; therefore, the upper limit of normal is 200 pg/mL for BNP and the corresponding value for NT-proBNP is 1200 pg/mL.[117] Moreover, concentrations of these biomarkers are influenced by age, sex, obesity, and other cardiac and noncardiac comorbidities. Asymptomatic patients with HF can also present with elevated BNP or NT-proBNP levels. This confounds the accurate interpretation of these markers and makes it challenging to integrate their usefulness into routine clinical practice. Elevated BNP and NT-proBNP have an established utility in ruling out HF in patients who present to the ED with SOB.[24] According to the ACC/AHA guidelines, measurement of BNP or NT-proBNP is useful for establishing prognosis or disease severity in chronic HF; however, the role of these biomarkers in reducing morbidity or mortality in HF is not well established. Several NP-guided therapy trials have been published.[118–120] The BNP- or NT-proBNP–guided HF therapy can be useful to achieve GDMT in selected clinically stable patients, but it is unclear if such an approach improves outcome. The *Guiding Evidence Based Therapy Using Biomarker Intensified Treatment in Heart Failure* (GUIDE-IT) study,[121] designed to assess the effects of NP-guided therapy in high-risk patients with LVSD, did not improve clinical outcomes between biomarker-guided treatment strategy versus usual care. It is still not clear when to use biomarkers to adjust HF medications. BNP levels may be elevated in patients

receiving ARNI because BNP is a substrate for neprilysin. Therefore, the 2021 update states that the utility of NP biomarker levels should be cautiously interpreted in patients on ARNI.[45] A.J.'s elevated BNP level, along with his clinical presentation, is indicative of HF exacerbation.

POTASSIUM SUPPLEMENTATION

Case 14-1, Question 9: The physician gave A.J. one 1-g dose of magnesium sulfate and three 20-mEq doses of potassium chloride IV. This raised his serum magnesium to 2.0 mEq/L and his potassium to 3.9 mEq/L. Should he receive prophylactic magnesium or potassium supplementation? What is an appropriate dose?

At this time, A.J. does not need further magnesium replacement, but his serum magnesium level should be measured again after he has received furosemide for a few days. If the level drops again, maintenance therapy with oral magnesium oxide tablets can be started.

A fall in serum potassium concentration can be seen within hours of the first dose of a diuretic, and the maximal fall usually is reached by the end of the first week of treatment. Potassium supplementation is not required in all patients receiving diuretics. They should be monitored frequently in the first few months of diuretic therapy to determine their potassium requirements. Similarly, when diuretics are stopped, it can take several weeks for serum potassium to return to baseline. Therefore, it is possible that A.J.'s admitting potassium level of 3.2 mEq/L reflects the nadir of his response to HCTZ. His initial response to potassium supplementation shows that his hypokalemia will be easily controlled. It might be argued that he should be observed for a few days and not given further supplements; however, because his diuresis is to be increased and if digoxin may later be considered, potassium supplementation is warranted. Long-term potassium supplementation may not be necessary with concomitant administration of ACEIs and AAs.

Because A.J. is started on furosemide, HCTZ should be discontinued. If hypokalemia persists, the AA dose can be uptitrated.

Dose requirements

It is difficult to predict the dose of potassium chloride that will be required to maintain proper potassium balance. Many patients do well with 20 mEq/day, but it is questionable how many patients need any supplement at all. People with well-documented hypokalemia can require anywhere from 20 to 120 mEq of potassium chloride per day.[122–124] Those patients with disease states associated with high circulating aldosterone levels require doses of potassium in excess of 60 mEq/day. In patients who need long-term potassium supplementation, efforts should be made to increase doses of ACEIs to target doses or maximal tolerated doses, and appropriate addition of an AA should be considered. However, a few selected patients may still need to take potassium supplementation, despite the addition of an AA.

MONITORING

Case 14-1, Question 10: After a single 40-mg IV dose of furosemide, A.J. is begun on 40 mg of furosemide each morning and potassium chloride tablets 20 mEq bid. How should his therapy be monitored?

A.J. needs to be monitored for both an improvement in his HF and for side effects (see **Tables 14-4** and **14-6**). Subjectively, the clinician should monitor for decreased pulmonary distress and an increased exercise tolerance, demonstrating control of HF. Objective monitoring parameters for disease control include weight loss (ideal, 1.10–2.20 pounds [0.5–1 kg]/day until ideal dry weight is achieved), a decrease in edema, flattening of neck veins, and disappearance of the S_3 gallop and rales. Because A.J. has HTN, his BP also requires monitoring, with a goal to reduce it to <130/80 mm Hg.

Table 14-6
Monitoring Parameters With Diuretics

↓CHF symptoms (see Table 14-4)
Weight loss or gain; goal is 1- to 2-lb (0.45- to 0.90-kg) weight loss/day until "ideal weight" achieved[a]
Signs of volume depletion
Weakness
Hypotension, dizziness
Orthostatic changes in BP[b]
↓Urine output
↑BUN[c]
Serum potassium and magnesium (avoid hypokalemia and hypomagnesemia)
↑Uric acid
↑Glucose

BP, blood pressure; BUN, blood urea nitrogen; HF, heart failure.

[a]Weight loss may be greater during the first few days when significant edema is present.

[b]A ↓ in systolic BP of 10 to 15 mm Hg or a ↓ in diastolic blood pressure (BP) of 5 to 10 mm Hg.

[c]A rising blood urea nitrogen (BUN) can be caused by either volume depletion from diuretics or poor renal blood flow from poorly controlled heart failure (HF). Small boluses of 0.9% saline can be given cautiously to differentiate a rising BUN from volume depletion versus poor cardiac output. If volume depletion is present, saline will cause an ↑ in urine output and a ↓ in BUN. However, if the patient has severe HF, the saline could cause pulmonary edema.

Patients are instructed to record their weight each day and are allowed to adjust their diuretic dose based on changes observed. If they are at their ideal "dry weight," they may reduce their dose of diuretic by 50% or even hold one or more doses. If weight increases >1 or 2 pounds (0.45 or 0.90 kg) in a day or 5 pounds (2.27 kg) per week, edema increases, or SOB returns, the dose of diuretic is temporarily increased.

Dizziness and weakness are subjective indices of volume depletion, hypotension, or potassium loss. Muscle cramps and

abdominal pain could indicate rapid changes in electrolyte balance. Objectively, a lowering of BP, especially on standing, and a rising BUN (prerenal azotemia) signify overdiuresis. Serum sodium, potassium, and uric acid should be monitored routinely. Questioning the patient with regard to the onset of diuresis (relative to drug ingestion) and the duration of the diuretic effect helps develop the most convenient and effective schedule for the patient.

CASE 14-1, QUESTION 11: If A.J.'s furosemide dose was increased to 80 mg twice a day without much response, what should be the next step?

REFRACTORY PATIENTS: COMBINATION THERAPY

All loop and thiazide diuretics must reach the tubular lumen to be effective. Because these drugs are highly bound to serum proteins and endogenous organic acids, they cannot enter the tubular lumen by glomerular filtration. For diuresis to begin, they must be transported into the proximal tubule by active secretion from the blood into the tubule. If this active transport is blocked, diuretics will not reach their site of action. This can lead to a diminished diuretic response in patients with either renal insufficiency or decreased RBF associated with decompensated HF. Patients with renal insufficiency or poor RBF often require large doses of diuretics to achieve a desired response. Endogenous organic acids can accumulate during renal insufficiency, avidly binding the drug and preventing its access to the site of action.[56,57] Both the total amount of drug delivered to the tubule and the rate of delivery of the drug to the tubule determine the magnitude of diuretic response elicited.[56,57] This explains why 80 mg of furosemide yields more diuresis than a 40-mg dose and why an IV injection provides a more rapid and vigorous diuresis than an oral dose. Once a threshold concentration (ceiling dose) is achieved within the tubule, higher concentrations produce no greater intensity of effect, but the duration of action may be prolonged.

Many patients exhibit a blunted diuretic response with continued therapy for unknown reasons. Generally, alternative treatment plans are pursued when the dose given approaches the ceiling doses for

each drug listed in **Table 14-3**. Continuous infusions of furosemide (5–15 mg/hour), bumetanide (0.5–1 mg/hour), or torsemide (3 mg/hour) can be more efficacious than are intermittent bolus doses in patients with severe HF or renal insufficiency.[56,57,125–127] Even higher doses have been recommended: 0.25 to 1 mg/kg/hour for furosemide, 0.1 mg/kg/hour for bumetanide, and 5 to 20 mg/hour for torsemide.[128] An aggressive protocol of a 100-mg IV bolus of furosemide followed by a continuous IV infusion at a rate of 20 to 40 mg/hour, which is doubled every 12 to 24 hours in unresponsive patients, to a maximal infusion rate of 160 mg/hour to attain a diuresis rate of ≥100 mL/hour has been described.[129]

In some instances, switching from one loop diuretic to another can overcome the problem.[129] For example, torsemide or bumetanide might work when furosemide fails because of more reliable absorption.[98,99] If this maneuver fails, a combination of diuretics can be tried. The most effective regimens combine drugs that work at two different parts of the tubule.[128] For example, a loop diuretic is used with metolazone, which blocks sodium reabsorption in the distal tubule. Various thiazide diuretics, including chlorthalidone, chlorothiazide, and HCTZ, have been reported to effectively enhance diuresis when combined with a loop diuretic. Triple-therapy regimens of metolazone, a loop diuretic, and an AA are used to optimize diuresis and electrolyte control.

Most clinicians choose a combination of metolazone plus furosemide or bumetanide. A wide range of metolazone dosages has been investigated.[130] Typically, a low dose of metolazone (2.5–5 mg) is first added to the furosemide therapy. Metolazone can be given intermittently (two to three times/week or as needed) to relieve congestion. The longer duration of action for metolazone can cause a greater than predicted diuresis and electrolyte loss when combined with a loop diuretic. Thus, careful monitoring of weight, urine output, BP, BUN, potassium, magnesium, and SCr is required. Because no parenteral form of metolazone exists, chlorothiazide, at a dose of 500 to 1000 mg once or twice daily, is an alternative to the thiazide diuretic that can be given intravenously. Although A.J.’s furosemide dose could be increased, metolazone 2.5 mg daily was added. A.J.

may also require additional doses of potassium supplementation to avoid hypokalemia with the addition of metolazone.

Angiotensin Converting Enzyme Inhibitors

AGENTS OF CHOICE

Case 14-1, Question 12: Along with furosemide, A.J. was started on 10 mg of lisinopril daily. Are there specific ACEIs approved for use in patients with HFrEF?

As a general rule, formulary decisions are first based on comparative pharmacologic activity, efficacy, and drug safety. Other factors to consider are labeled (FDA approved) indications, convenience of dosing schedule, and—all else being equal—the cost to the institution and the patient. HTN is the primary indication for all of the ACEIs. Not all ACEIs have an indication for HF.

ACEIs inhibit ACE (also called kinase II), reducing the activation of angiotensin II, a major contributor to the undesired hemodynamic responses to HF. Decreased circulating levels of NE, vasopressin, neurokinins, luteinizing hormone, prostacyclin, and NO also have been noted after administration of ACEIs.

In addition, ACE is responsible for degradation of bradykinin, substance P, and, possibly, other vasodilatory substances unrelated to angiotensin II. Thus, part of the beneficial effects of ACEIs is caused by the accumulation of bradykinin (**Fig. 14-8**). After attaching to bradykinin-2 (B_2) receptors, vasodilation is produced by stimulating the production of arachidonic acid metabolites, peroxidases, NO, and endothelium- derived hyperpolarizing factor in the vascular endothelium. In the kidney, bradykinin causes natriuresis through direct tubular effects.

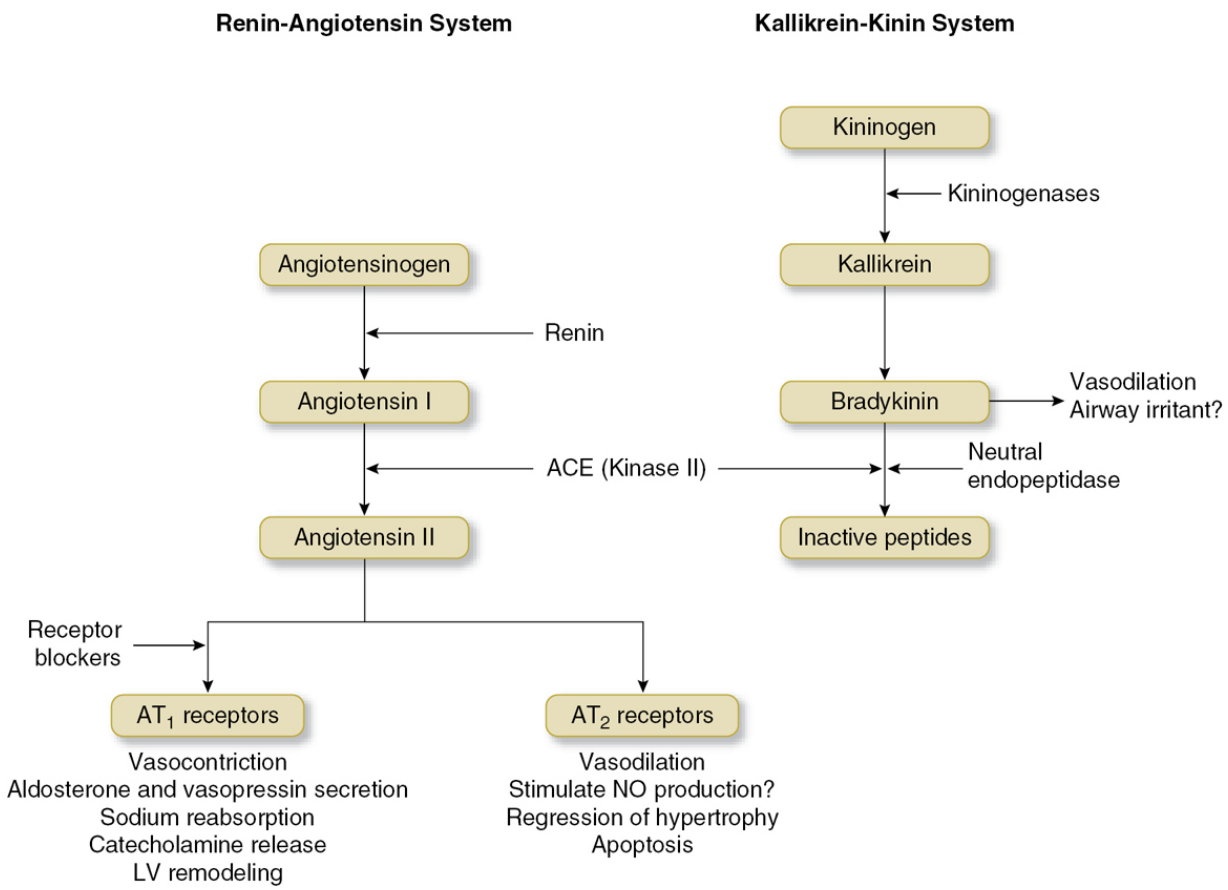

Figure 14-8 Angiotensin receptor blocker mechanism. ACE, angiotensin converting enzyme; LV, left ventricular; NO, nitric oxide.

The net effect is that ACEIs regulate the balance between the vasoconstrictive and salt-retentive properties of angiotensin II and the vasodilatory and natriuretic properties of bradykinin. The effects of ACEIs are reduced pulmonary capillary wedge pressure (PCWP; preload) and lowered SVR and systolic wall stress (afterload). CO increases without an increase in HR. ACEIs promote salt excretion by augmenting RBF and reducing the production of aldosterone and ADH. The beneficial effects on RBF, coupled with the drug's indirect inhibition of aldosterone, lead to a mild diuretic response, a distinct benefit compared to hydralazine.

Vasodilation and diuresis are not the only values of ACEIs in HF. Angiotensin II enhances vascular remodeling, whereas bradykinin impedes this process.[60,131] ACEIs impede ventricular remodeling by blocking the effects of angiotensin II on cardiac myocytes. Evidence

as to whether preserving bradykinin levels affects remodeling is inconclusive, although it might attenuate the progressive deposition of collagen during the chronic phase of post-MI cardiac remodeling.

Individual ACEIs with FDA-labeled approvals for the treatment of HF or LV dysfunction after MI are included in **Table 14-7**. There is no reason to favor one ACEI over another except in the case of optimizing dosing schedules for patients and trying to use once-daily dosing, if possible, to improve medication adherence rates.

Table 14-7

Angiotensin Converting Enzyme Inhibitor Dosing in Heart Failure With Reduced Ejection Fraction

Drug	Available Dosage Form	Initial Dose[a]	Maximal Dose
Captopril[b]	12.5, 25, 50, 100 mg tablets	6.25–12.5 mg tid	100 mg tid
Enalapril[c]	2.5, 5, 10, 20 mg tablets	2.5–5 mg every day	20 mg bid
Fosinopril	10, 20, 40 mg tablets	5–10 mg every day	40 mg every day
Lisinopril	2.5, 5, 10, 20, 40 mg tablets	2.5–5 mg every day	40 mg every day
Quinapril[c]	5, 10, 20, 40 mg tablets	5–10 mg every day	20 mg bid
Perindopril	2, 4, 8 mg tablets	2 mg every day	16 mg every day
Ramipril[c]	1.25, 2.5, 5, 10 mg capsules	1.25–2.5 mg every day	10 mg bid
Trandolapril	1, 2, 4 mg tablets	1 mg every day	8 mg every day

Benazepril, cilazapril, moexipril, perindopril, ramipril, and trandolapril are not labeled for use in heart failure.

ACE, angiotensin converting enzyme; bid, two times a day; tid, three times a day.

[a]Start with lowest dose to avoid bradycardia, hypotension, or renal dysfunction. All but captopril given every day in the morning at starting doses. Increase dose slowly at 2- to 4-week intervals to assess full effect and tolerance.

[b]Captopril is short acting. Start with a 6.25- or 12.5-mg test dose, then 6.25 to 12.5 mg three times a day (tid).

[c]Enalapril, quinapril, and ramipril could possibly be given every day instead of two times a day (bid) based on half-life.

Numerous placebo-controlled trials have documented the favorable effects of ACEI therapy on hemodynamic variables, clinical status, and symptoms of HF,[132,133] and demonstrated a consistent 20% to 30% relative reduction in HF mortality. ACEI therapy is generally better than are other vasodilator regimens, including the hydralazine–nitrate combination or ARBs after considering efficacy and tolerability.

Table 14-8 provides a brief summary of the results of the key ACEI HFrEF trials.[17,66,67,133–135] Of the five approved agents, the best evidence for improved survival is available for enalapril in both chronically symptomatic patients (NYHA classes II–IV) and asymptomatic patients with evidence of an impaired EF after an MI.[136–139]

Table 14-8
Clinical Trials of Angiotensin Converting Enzyme Inhibitors in Heart Failure With Reduced Ejection Fraction

Study	Patient Population	ACEI	Time Started After MI	Treatment Duration	Outcome
Studies in LV Dysfunction					
CONSENSUS[137]	NYHA IV (N = 253)	Enalapril vs placebo		1 day–20 months	Decreased mortality and HF
SOLVD-Treatment[134]	NYHA II/III (N = 2569)	Enalapril vs placebo		22–55 months	Decreased mortality and HF
V-HeFT II[253]	NYHA II/III (N = 804)	Enalapril vs hydralazine, isosorbide		0.5–5.7 years	Decreased mortality and sudden death
SOLVD-Prevention[315]	Asymptomatic LV dysfunction (N = 4228)	Enalapril vs placebo		14.6–62 months	Decreased mortality and HF hospitalizations
Studies in LV Dysfunction After MI					
SAVE[314]	MI, decreased LV function (N = 2331)	Captopril vs placebo	3–16 days	24–60 months	Decreased mortality
CONSENSUS II[316]	MI (N = 6090)	Enalaprilat/enalapril vs placebo	24 hours	41–180 days	No change in survival; hypotension with enalaprilat
AIRE[317]	MI and HF (N = 2006)	Ramipril vs placebo	3–10 days	>6 months	Decreased mortality
ISIS-4[318]	MI (N > 50,000)	Captopril vs placebo	24 hours	28 days	Decreased mortality
GISSI-3[319]	MI (N = 19,394)	Lisinopril vs placebo	24 hours	6 weeks	Decreased mortality
TRACE[320]	MI, decreased LV function (N = 1749)	Trandolapril vs placebo	3–7 days	24–50 months	Decreased mortality
SMILE[321]	MI (N = 1556)	Zofenopril vs placebo	24 hours	6 weeks	Decreased mortality

The ACC/AHA guidelines recommend selecting an ACEI that has shown reductions in both morbidity and mortality in clinical trials in HFrEF. The following ACEIs are considered first-line options based on clinical trials: captopril, enalapril, fosinopril, lisinopril, perindopril, quinapril, ramipril, or trandolapril.[1,11,45]

Captopril and lisinopril are both active as the parent compound and do not have active metabolites. All other ACEIs are prodrugs that require enzymatic conversion to active metabolites. Captopril has a short duration of action, necessitating three times daily administration in most patients. Although this characteristic may be advantageous when initiating therapy by allowing closer assessment of early side effects, for chronic maintenance, it is preferable to use a drug that can be given either once or twice daily. All other ACEIs meet this criterion. Package insert labeling and common standards of practice have led to twice-daily dosing, especially at higher doses, for enalapril, quinapril, and ramipril.

A.J.'s physician chooses to start lisinopril 10 mg daily based on evidence of clinical efficacy, improved survival, and availability as a generic medication. If there were concerns about hypotension, then captopril would be preferred during the initial 1 to 2 days of initiation therapy to avoid dropping the patient's BP too quickly.

Dose–response relationships

Case 14-1, Question 13: What is the target dose of lisinopril in A.J.? Do all patients need to be titrated to target doses?

Clinical evidence shows a relationship between the degree of improvement in HF symptoms and the dose of drug given. Larger doses are more likely to improve the patient's quality of life and reduce the incidence of hospital stays, but the impact of larger doses on mortality is less clear. At the same time, higher doses are associated with a greater risk of side effects. Based on these principles, proposed recommended starting and maximal doses for the ACEIs are listed in **Table 14-7**.[1]

The guidelines recommend that ACEIs be initiated at low doses and titrated to the maximal tolerated target dose. Supporting this principle are the results of the Assessment of Treatment with Lisinopril and Survival trial.[140,141] Lisinopril 2.5 to 5 mg (low dosage) or 32.5 to 35 mg (high dosage) was given to over 3000 patients. All-

cause mortality did not differ significantly between the two groups. In the high-dose group, hospitalizations and the combined end point of death and hospitalization were reduced by 24% (P = .003) and 12% (P = .002), respectively. The higher dose was tolerated by 90% of patients assigned this dose.

Despite these recommendations for using the highest tolerated doses, evidence also suggests that lower doses are beneficial. The UK Heart Failure Network Study found that 10 mg of twice-daily enalapril was no more effective than was 2.5 mg bid.[142] Mortality, evaluated separately, was 4.2%, 3.3%, and 2.9%, for low (2.5 mg bid), moderate (5 mg bid), and higher (10 mg bid) dosages, respectively, and not significantly different. The guidelines recommend prescribing doses that have reduced the risk of CV events in clinical trials, and if the trial doses cannot be achieved, then lower doses should be used.

For lisinopril, the recommended starting dosage is 2.5 to 5 mg/day. For older patients or those with other risk factors (systolic blood pressure [SBP] <100 mm Hg, those taking large doses of diuretics, or those with preexisting hyponatremia, hyperkalemia, or renal insufficiency), the starting dose of 2.5 mg/day would be more appropriate. This dose, or an equivalent with one of the other drugs, should be considered if the patient is being started directly on a long-acting drug without prior titration on captopril. For a patient such as A.J. who has already been treated with captopril for 2 days with no evidence of intolerance, a 10-mg dose is appropriate.

The long-term target maximum dosage of lisinopril for A.J. is 40 mg daily. No clear formula exists for deciding how quickly to titrate to this dose. It depends on the degree of reduction in his HF symptoms and side effects and the motivation to take the medication. Whenever dosage adjustments are made, it may take as few as 24 hours for the patient to perceive symptom reduction, but generally full hemodynamic affects are not reached for 1 to 2 months. Hypotension and other side effects are more immediate. A.J. should have his dose reassessed in 1 to 2 weeks to determine whether he can tolerate a dosage increase to 20 mg daily. An SCr and potassium should be ordered at this time to assess the safety of

titrating the ACEI. Thereafter, a doubling of the dose could occur every 2 to 4 weeks. Thus, it could take 2 months to titrate upward to 40 mg daily. If A.J.'s symptoms do not improve, but he has no side effects, titration can occur more quickly either by shortening the assessment periods (eg, every week) or by using larger dose increments.

ANGIOTENSIN RECEPTOR BLOCKERS

CASE 14-1, QUESTION 14: When should an ARB be used in A.J.?

Several clinical trials in HF have shown the therapeutic benefit of ARBs in modifying HF symptoms (**Table 14-9**).[143–150] A meta-analysis combined data on all-cause mortality and HF-related hospitalizations from a total of 17 clinical trials comparing an ARB with either placebo or an ACEI in patients with HF.[142] ARBs favorably improved exercise tolerance and EF compared with placebo. However, they were not superior to ACEIs in reducing all-cause mortality or hospitalizations for HF.

Table 14-9
Clinical Trials of Angiotensin Receptor Blockers in Heart Failure

Trial	Patient Population	ARB	Treatment Duration	Outcome
ELITE[148]	NYHA II–IV (*N* = 722) EF ≤40%	Losartan (50 mg every day) or captopril (50 mg tid)	48 weeks	No significant difference was observed for the primary end point (persistent renal dysfunction) or the secondary end point (composite of death/HF admissions). Losartan was associated with a lower mortality than was captopril.
RESOLVD[150]	NYHA II–IV (*N* = 768) EF ≤40%	Candesartan (4, 8, or 16 mg), or candesartan (4 or 8 mg) + 20 mg enalapril, or 20 mg enalapril	43 weeks	Combination has greater benefits on LV remodeling. No difference in mortality No difference in NYHA class, QoL, 6-minute walking distance
ELITEII[149]	NYHA II–IV (*N* = 3152) EF ≤40%	Losartan (50 mg every day) or captopril (50 mg tid)	48 weeks	Losartan was not superior to captopril in improving survival but was significantly better tolerated. A subgroup analysis of ELITE II found a greater risk of death when losartan was used in addition to β-blockers.
Val-Heft[151]	NYHA II–IV (*N* = 5010) EF <40%	Valsartan 160 mg bid or placebo bid	23 months	There was no difference in mortality between the two groups. In patients previously receiving both ACEI and a β-blocker (*N* = 1610), the risk of death was increased with the addition of valsartan.
CHARM[153] Alternative	NYHA II–IV (*N* = 2028) EF ≤40%	Candesartan (32 mg) vs placebo	34 months	23% reduction in CV mortality or HF hospitalization favoring the candesartan group. More side effects in the candesartan group (hypotension, hyperkalemia, ↑ SCr) vs placebo
CHARM[154] Added	NYHA II–IV (*N* = 2548) EF ≤40%	Candesartan (32 mg) + ACEI vs placebo	41 months	15% risk reduction in CV mortality or HF admissions compared with placebo. However, there were more side effects in the candesartan group (hypotension, hyperkalemia, ↑ SCr) vs placebo.
CHARM[156] Overall	NYHA II–IV (*N* = 7599)	Candesartan (32 mg) vs placebo	38 months	There was no overall difference in primary outcome of all-cause death.

ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker; bid, two times a day; CV, cardiovascular; EF, ejection fraction; HF, heart failure; LV, left ventricular; NYHA, New York Heart Association; QoL, quality of life; SCr, serum creatinine; tid, three times a day.

The first major clinical trial comparing an ARB with an ACEI in patients with HF was the *E*valuation of *L*osartan *I*n *T*he *E*lderly (ELITE) study.[149] Losartan was compared to captopril. For the primary end point, a sustained increase in renal function decline, the two drugs performed identically with 10.5% of subjects in each group having a >0.3 mg/dL rise in SCr. An unexpected finding was an insignificant trend toward more deaths from all causes in the captopril group (8.7%) compared with losartan (4.8%).

The follow-up ELITE II trial was specifically designed to test the hypothesis that losartan was superior to captopril in terms of reduction in mortality and morbidity in patients age 60 years and older.[145] No significant difference was seen in all-cause mortality, sudden death, or all-cause mortality plus hospitalization. Although

ARB treatment was not superior to ACEI therapy, it was better tolerated. Specifically, significantly fewer patients experienced cough with the ARB.

The Valsartan Heart Failure Trial (Val-HeFT) was a double-blind, placebo-controlled study to measure the morbidity and mortality in patients with HFrEF given valsartan.[151] Patients were randomly assigned to receive valsartan or placebo twice daily. There was no significant difference in all-cause mortality between the valsartan group (19.7%) and the control group (19.4%). Nearly 93% of patients in both groups were receiving an ACEI. Dizziness, hypotension, and renal impairment all occurred more frequently in those treated with valsartan.

Further, post hoc analysis found that within the 35% of subjects taking the combination of an ACEI and a β-blocker at baseline, the addition of valsartan as a third drug was associated with a trend toward increased morbidity and a statistically significant increase in the combined end point of mortality and morbidity. The overall study results suggested that a combination of valsartan and an ACEI reduces morbidity, but not mortality. More worrisome was the implication that the three-drug combination of valsartan, an ACEI, and a β-blocker adversely affects morbidity and mortality.[154]

The *VAL*sartan *I*n *A*cute myocardial i*N*farc*T*ion (VALIANT) trial of stable patients after MI with LV dysfunction was designed to test the hypothesis that valsartan alone and in combination with captopril (an ACEI) would improve survival. In VALIANT, 70% of the patients were also receiving β-blockers. All-cause mortality, the primary end point, was identical in all groups. In addition, an increased rate of side effects was seen in the combination ACEI/ARB group. Interestingly, among the subgroup of patients taking β-blockers, no evidence was found of harmful interaction with triple therapy.[152] As a result of the VALIANT trial, the FDA approved the use of valsartan in patients at high risk after a heart attack, and in those with HF.

The best evidence addressing the efficacy and safety of ARB in HF comes from a series of three investigations known collectively as the CHARM trial. The individual components of the CHARM Program are (a) CHARM-Alternative, (b) CHARM-Added, and (c) CHARM-

Preserved.[153–155] All three investigations were randomized, double-blind, placebo-controlled trials that enrolled adult patients (age older than 18 years) with at least a 4-week history of symptomatic (NYHA classes II–IV) HF. Subjects randomly assigned to candesartan were started on 4 mg and titrated to 32 mg once daily, as tolerated. Some standard therapy (diuretics, β-blockers, digoxin, spironolactone, and ACEI) was continued. For all three trials, the primary end point was the combined incidence of CV death, HF hospitalizations, or both. The differences in admission criteria and outcomes among the individual trials are discussed here.

CHARM-Alternative enrolled 2028 subjects who met all of the inclusion criteria defined earlier plus two additional criteria: an EF of ≤40% and intolerance of ACEIs (cough, 72%; hypotension, 13%; renal dysfunction, 12%). Thus, subjects in this group received either an ARB alone or a placebo without an ACEI. A 23% reduction was found in the primary outcome of CV death, hospital admission for HF, or both in the candesartan group compared with placebo. The overall incidence of drug discontinuations because of adverse events was not statistically different between candesartan and placebo, but there were significantly more reports of symptomatic hypotension, increased creatinine levels, and hyperkalemia in those treated with candesartan (**Table 14-10**).

Table 14-10
Adverse Events That Lead to Permanent Drug Discontinuation

Trial	Outcomes	Candesartan (%)	Placebo (%)	P Value
CHARM-Alternative[151]	Any adverse event or laboratory abnormality	21.5	19.3	.23
	Hypotension	3.7	0.9	<.0001
	Increased creatinine	6.1	2.7	<.0001
	Hyperkalemia	1.9	0.3	.0005
CHARM-Added[152]	Any adverse event or laboratory abnormality			.0003
	Hypotension	4.5	3.5	.079
	Increased creatinine	7.8	4.1	.0001
	Hyperkalemia	3.4	0.7	<.0001
CHARM-Preserved[153]	Any adverse event or laboratory abnormality	17.8	13.5	.001
	Hypotension	2.4	1.1	.006
	Increased creatinine	4.8	2.4	<.001
	Hyperkalemia	1.5	0.6	.019
CHARM-Overall[154]	Any adverse event or laboratory	21	16.7	<.001

	abnormality			
	Hypotension	3.5	1.7	<.0001
	Increased creatinine	6.2	3.0	<.0001
	Hyperkalemia	2.2	0.6	<.0001

The CHARM-Added trial attempted to determine whether the combination of an ACEI plus an ARB offered any clinical advantages compared with an ACEI alone in patients with symptomatic HF with an EF of ≤40%. At baseline, 55% of the patients were treated with β-blockers and 17% with spironolactone. The addition of candesartan to an ACEI and other usual HF treatments led to a 15% relative risk (*P* = .011) reduction in the primary outcome of CV death, hospital admission for HF in the combination group compared to the ACEI-alone group. It is interesting to compare the result of the CHARM-Added trial with those of the Val-HeFT study. In Val-HeFT, 93% of the subjects receiving the ARB valsartan were concurrently receiving an ACEI. The combined end point of morbidity and mortality was significantly reduced with combination therapy in Val-HeFT, but mortality alone was not reduced. A trend toward more deaths in the small subgroup receiving the triple combination of a β-blocker with an ACEI and ARB was observed, whereas β-blocker use had no adverse effect in CHARM-Added.

The combined results of all three CHARM components (CHARM-Added, CHARM-Alternative, and CHARM-Preserved; see discussion of CHARM-Preserved in Case 14-7, Question 1) were reported in the CHARM-Overall trial.[156] This composite analysis evaluates the benefits of candesartan in symptomatic patients with HF, regardless of LV systolic function. A different primary end point was chosen for the CHARM-Overall analysis: all-cause death. Although the combined results failed to detect a clinically significant reduction in all-cause death between candesartan and placebo (9% reduction; *P* = .32), significant reductions were seen in CV death (12%), hospital admission for HF (21%), and combined CV death or hospital

admission for HF (16%), which was the primary end point for the individual trials.

The collective results of the CHARM program reinforce the conclusion that ARBs can reduce morbidity and mortality in symptomatic patients with HFrEF, and they can be safely used in patients who are intolerant of ACEI therapy. Combination therapy (ACEI plus ARB) with concomitant use of β-blockers appears to be beneficial and safe, as long as patients are closely monitored for adverse effects. Current guidelines recommend the addition of an AA over ARB in patients receiving an ACEI and β-blockers.

Because ELITE II failed to demonstrate any survival benefits of losartan 50 mg/day, over captopril 150 mg/day in patients with HFrEF, the **H**eart failure **E**ndpoint evaluation of **A**ngiotensin II **A**ntagonist **L**osartan (HEAAL) study was designed to compare the effect of two doses of losartan (50 vs 150 mg daily) on the combined end point of all-cause mortality and hospitalizations in HFrEF. A median follow-up of 4.7 years showed losartan 150 mg daily reduced the rate of death or HF admission when compared with losartan 50 mg daily. The high-dose group experienced more renal dysfunction, hypotension, and hyperkalemia, although these results did not lead to significantly more treatment discontinuations. Old age, concomitant AA dose, and baseline levels of potassium and SCr were common predictors of adverse events and resulted in increased mortality among patients who experienced these adverse events. Therefore, dose titrations should be done with close monitoring, especially in individuals at high risk for developing adverse events.[157]

In summary, ARB HF trials demonstrate survival benefits in HFrEF in patients who are ACEI intolerant or as an add-on therapy to ACEIs and β-blockers. However, current guidelines do not recommend the routine use of triple therapy, and A.J. should not be started on an ARB in addition to his lisinopril. If A.J. develops a cough on lisinopril, he can be switched to an ARB such as candesartan.

Side Effects

ANGIOTENSIN CONVERTING ENZYME INHIBITOR–INDUCED COUGH

Case 14-1, Question 15: A.J. presents to the outpatient HF clinic with an annoying productive cough after 6 weeks of lisinopril therapy. His chest examination reveals no evidence of wheezing, with only a few crackles, his neck veins are only minimally elevated over normal, his ankle edema is 1+, and his weight is stable. All laboratory values are normal. Could the cough be a symptom of his HF or is it ACEI induced? What are the recommendations for managing an ACEI-induced cough?

Cough can be a sign of HF in patients with pulmonary congestion. In extreme cases, patients have "cardiac asthma" with severe air hunger, wheezing, and dyspnea. However, A.J.'s HF is much improved as evidenced by the objective data. The absence of wheezing and no prior history of asthma or smoking make an obstructive airways disease (asthma or COPD) unlikely. It is possible that he does have bronchitis, but he does not report having a cold or other respiratory illness preceding the cough. Without other causes, an ACEI-induced cough is most likely.

This side effect occurs with all ACEIs.[158] Cough is a well-established complication of ACEIs and presents as dry and nonproductive; sometimes described as a "tickle in the back of the throat." This complication can arise within hours of the first dose, or it can present after weeks to months of treatment. Although resolution of the cough usually occurs within 1 to 4 weeks, in some patients it can persist up to 3 months after discontinuation of therapy.

Bradykinin accumulation within the upper airway and decreased metabolism of proinflammatory mediators such as substance P or prostaglandins are proposed mechanisms of ACEI-induced cough. These chemicals then act as irritant substances in the airways to increase bronchial reactivity and induce coughing.

Various case reports have found an incidence of cough in 5% to 35% of all patients. The incidence is dose independent.[159] One investigator found a 5% to 10% incidence in White patients of European descent that rose to nearly 50% in Chinese patients.[160]

There may also be a higher incidence in females and Black populations.[157]

Because this is a pharmacologic effect rather than an allergic reaction, dose reduction or switching from one ACEI to another is generally not helpful. The only way to definitively diagnose the drug-induced cough is to discontinue therapy. Even then, false-positive results can occur if the patient had a mild case of bronchitis that spontaneously resolved at about the same time that the ACEI was discontinued. If the cough persists after drug discontinuation, other causes should be investigated such as coexisting gastroesophageal reflux disease or allergic rhinitis.

For patients with persistent cough, ARB or hydralazine–isosorbide is a safe alternative. Therefore, A.J. can continue taking lisinopril for another couple of weeks to determine whether the cough will resolve on its own. His symptoms of HF have abated since the initiation of ACEI therapy, and the cough may be no more than an annoyance. He is not at risk for experiencing asthma or other airway problems. If his cough persists, an ARB is probably the best alternative.

OTHER ANGIOTENSIN CONVERTING ENZYME INHIBITOR AND ANGIOTENSIN RECEPTOR BLOCKER SIDE EFFECTS

Hyperkalemia

Case 14-1, Question 16: What other side effects of both ACEIs and ARBs need to be monitored? Does changing from an ACEI to an ARB reduce the risk of any of these side effects?

ACEIs and ARBs have the potential to raise serum potassium concentrations via indirect aldosterone inhibition and other neurohormonal actions.[161,162] For most patients, the magnitude of increase in serum potassium concentration from ACEIs and ARBs alone is relatively small, but the risk of developing hyperkalemia is greater if the patient has compromised renal function or advanced HF. Combination therapy of an ACE or ARB with potassium

supplements, or potassium-sparing diuretics, further accentuates the risk of hyperkalemia.

Several case reports and case series have reported hyperkalemia and hospitalizations secondary to spironolactone in patients with HF. This became more evident as prescribing patterns for spironolactone dramatically increased after publication of the RALES study.[163] Not only was there a significant increase in the number of prescriptions for spironolactone for patients with HF, but doses higher than those recommended by the clinical trials were often used, especially in patients with evidence of preexisting renal dysfunction. In addition, evidence indicated inadequate monitoring of serum potassium, renal function, and concomitant drug therapy. Although concurrent use of a potassium-wasting diuretic (thiazide or loop diuretic) may counteract potassium retention from spironolactone or other drugs (ACEIs, ARBs), it is nearly impossible to predict who will exhibit hypokalemia, hyperkalemia, or remain normokalemic.[164,165] Each patient must be assessed individually for personal response to various drug combinations. Close monitoring of serum potassium is required; potassium levels and renal function should be checked in 3 days and at 1 week after initiation of therapy known to affect potassium and at least monthly for the first 3 months (**Table 14-11**).

Table 14-11
Various Causes of Hyperkalemia and Strategies to Minimize Risk

Cause	Mechanism	Strategies to Minimize Risk
Aldosterone blockers	Decreased levels of aldosterone and subsequent potassium retention	GFR should be determined and aldosterone antagonist should be avoided if creatinine clearance is <30 mL/minute and baseline serum potassium is >5.0 mEq/L. An initial dose of spironolactone 12.5 mg

		or eplerenone 25 mg is recommended, after which the dose may be increased to spironolactone 25 mg or eplerenone 50 mg if appropriate. Close monitoring of serum potassium is required; potassium levels and renal function should be checked in 3 days and at 1 week after initiation of therapy and at least monthly for the first 3 months.
RAAS blockade by ACEIs and ARBs Note: risk increases at higher doses (enalapril or lisinopril ≥10 mg/day)	Inhibition of angiotensin II production or receptor binding reduces the delivery of sodium and water to the distal nephron, which, in combination with hypoaldosteronism, promotes hyperkalemia.	Doses of drugs should be decreased as appropriate.
NSAIDs	Inhibit renal prostaglandin synthesis (PGE_2 and PGI_2), resulting in hyporeninemic hypoaldosteronism. Decreased availability of sodium for exchange with potassium at distal tubular sites	NSAIDs and cyclooxygenase-2 inhibitors should be avoided.
Potassium-sparing diuretics, cyclosporine, tacrolimus, trimethoprim, and heparin	Decreased excretion of potassium	Close monitoring of serum potassium is required. Doses of drugs known to cause hyperkalemia should be decreased as appropriate.
Patients who have increased dietary	In the presence of renal insufficiency, decreased	Potassium supplements should be discontinued

potassium intake, use salt substitutes (a rich source of potassium), or take potassium supplements in combination with aldosterone antagonists	potassium excretion occurs.	or reduced. Patients should be educated on foods rich in potassium and to avoid salt substitutes.
Patients with HF with diabetes taking aldosterone antagonists	Hyporeninemic hypoaldosteronism leading to decreased levels of aldosterone and subsequent potassium retention Insulin deficiency can stimulate the shift of potassium to the extracellular space.	Hyperglycemia should be monitored, and appropriate drug therapy should be determined to treat diabetes.
Advanced age, low muscle mass, or renal insufficiency (serum creatinine >1.6 mg/dL)	Impaired release of renin resulting in hypoaldosteronism SCr may not accurately reflect GFR. Risk of hyperkalemia increases progressively as SCr rises.	GFR should be determined and doses adjusted accordingly.

ACEIs, angiotensin converting enzymes; ARBs, angiotensin receptor blockers; GFR, glomerular filtration rate; HF, heart failure; NSAIDs, nonsteroidal anti-inflammatory drugs; PGE_2, prostaglandin E_2; PGI_2, prostaglandin I_2; RAAS, renin–angiotensin–aldosterone system; SCr, serum creatinine.

Angioedema

Angioedema (angioneurotic edema) is a severe, potentially life-threatening complication of ACEI treatment.[166–168] Characterized by facial and neck swelling, with obstruction to airflow by laryngeal and bronchial edema, this reaction resembles anaphylaxis. The mechanism of ACEI induction of angioedema is unknown but is thought to be hypersensitivity to accumulated vasodilating kinins.

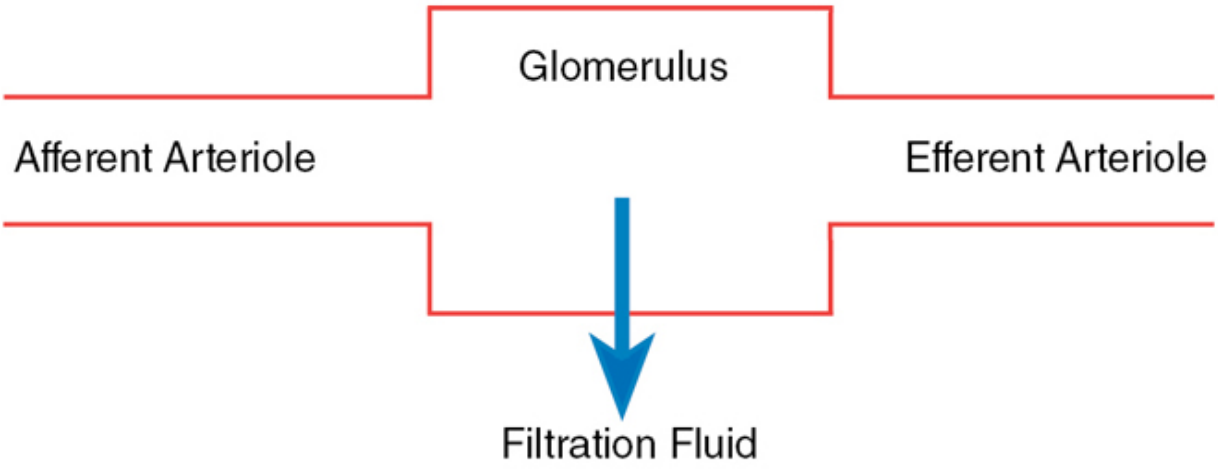
Some, but not all, persons with drug-induced angioedema have a history of familial angioedema associated with a genetic defect in their complement system. In most cases, angioedema reactions occurred within 1 month of starting therapy, but can also present after several months of therapy, although infrequent.[167] Black patients and females may have a higher prevalence. Of concern is the observation that ACEI-induced angioedema is often misdiagnosed.[168] It is prudent to avoid all ACEIs in any patient with a history of angioedema from any cause.

Because the mechanism of ACEI-induced angioedema is thought to be caused by kinin accumulation, changing to an ARB might be an option.[169] Several case reports, however, have implicated candesartan, losartan, and valsartan as possible causative agents of angioedema.[166,170–173] In some cases, the subjects had previously experienced angioedema with an ACEI (indicating possible cross-reactivity), whereas others were ACEI naive. A small but potential risk for ARB-induced angioedema in patients who are ACEI intolerant comes from the CHARM-Alternative trial.[153] Of 39 patients with a history of angioedema while taking an ACEI, 3 experienced angioedema on candesartan, although only 1 of the 3 actually discontinued taking candesartan. For now, it is prudent to assess risk–benefit, and ARBs should be used cautiously in the management of patients who have angioedema from ACEIs.

Effects of angiotensin converting enzyme inhibitors and angiotensin receptor blockers on kidney function

As seen in **Figure 14-9**, glomerular filtration is optimal when intraglomerular pressure is normal. The balance between afferent flow into the glomerulus and efferent flow exiting the glomerulus determines the intraglomerular pressure. A drop in afferent flow or pressure occurring as a result of hypotension, volume loss, hypoalbuminemia, decreased CO, or obstructive lesions such as renal artery stenosis can significantly lower intraglomerular pressure and lead to impaired renal function. Similarly, long-standing HTN can

damage glomerular basement membrane capillaries and cause renal insufficiency.



↓ Afferent flow to glomerulus caused by:

- ↓ Cardiac output
  - Systemic hypotension
  - Blood loss
  - Overdiuresis, dehydration
- Renal artery stenosis (obstruction)
- Inhibition of PGE from NSAIDs

↑ Afferent flow to glomerulus caused by:

- Systemic hypertension

↑ Efferent pressure to maintain glomerular pressure if:

- ↑ Production of angiotensin II via activation of renin-angiotensin system

↓ Efferent pressure to protect glomerular pressure if:

- ACE inhibitors block angiotensin II production

Figure 14-9 Factors affecting renal blood flow. Glomerular filtration is optimal when adequate hydrostatic pressure is maintained in the glomerulus. Governing factors include the blood flow rate to the glomerulus and the balance of afferent and efferent arteriole dilation and constriction. ACE, angiotensin converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs; PGE, prostaglandin E.

In the case of low-pressure or low-flow states, the RAAS is activated to maintain intraglomerular pressure. A key factor in preserving glomerular pressure is *efferent vasoconstriction* mediated by angiotensin II. Increased efferent pressure helps maintain intraglomerular pressure by impeding blood flow out of the glomerulus. When patients with low-pressure states are given ACEIs or ARBs, the protective mechanism of efferent vasoconstriction is inhibited and GFR decreases to a modest degree, resulting in an increase in SCr.

By decreasing afterload, CO may improve after ACEI or ARB therapy, thus preserving or even enhancing RBF. If, however, starting ACEIs or ARBs leads to a rapid decrease in systemic BP that is not followed by an increase in CO, worsening renal function may ensue. It is impossible to predict which event will occur. Therefore, ACEI or ARB therapy needs to be started with low doses, and careful monitoring of the BP and renal function should occur as dosages are increased. Renal function and BP should be checked before and 1 to 2 weeks after initiation or dose increase. Patients with risk factors such as preexisting renal insufficiency or concomitant treatment with NSAIDs or high-dose diuretics may require more frequent monitoring. Diuretics are not contraindicated, but the diuretic dosage may need to be reduced to avoid overly aggressive diuresis and the accompanying volume depletion and hypotension. The guidelines recommend caution when prescribing ACEIs/ARBs in patients who have low SBPs (80 mm Hg), increased SCr (>3 mg/dL), bilateral renal artery stenosis, or serum potassium >5.0 mEq/L.[1]

Use of a-Blockers in Heart Failure With Reduced Left Ventricular Ejection Fraction

Case 14-1, Question 17: After 3 days of furosemide and an ACEI, A.J.'s PND has resolved, but he still has difficulty walking without SOB and fatigue. His lower extremity edema has been significantly reduced. His current BP is 145/90 mm Hg, his pulse is 82 bpm, and his weight has dropped to 160.94 pounds (73

kg) after diuresis. Repeat laboratory measurements include the following results:

Na, 139 mEq/L
K, 4.3 mEq/L
Cl, 98 mEq/L
CO_2, 27 mEq/L
BUN, 27 mg/dL
SCr, 0.6 mg/dL

The medical team has decided to discharge A.J. soon. You recommend that A.J. should be started on a β-blocker before discharge. What is your rationale?

β-Blockers have been evaluated during randomized clinical trials in >20,000 patients with varying degrees of HFrEF. Five meta-analyses have arrived at the same conclusions: the use of three β-blockers (bisoprolol, metoprolol succinate, or carvedilol) is associated with a consistent 30% reduction in mortality and a 40% reduction in hospitalizations in patients with HF.[174–178]

The ACC/AHA guidelines recommend bisoprolol, metoprolol succinate, or carvedilol for all patients with HFrEF unless there is a contraindication to their use or the patient is unable to tolerate treatment with a β-blocker.[11] They should be a part of the primary treatment plan with an ACEI or ARB. Patients should receive a β-blocker to slow the rate of disease progression and reduce the risk of sudden death. Patients do not need to be taking high doses of ACEIs before being considered for treatment with a β-blocker. To the contrary, in patients taking a low dose of an ACEI, the addition of a β-blocker produces a greater reduction in symptoms and in the risk of death than an increase in the dose of an ACEI. β-Blockers should be initiated before discharge in the vast majority of patients hospitalized for HF.[179] Only those clinically unstable patients who are hospitalized in an intensive care unit, require IV positive inotropic support, have severe fluid overload or depletion, have symptomatic bradycardia or advanced heart block that is not treated with a pacemaker, or have a history of poorly controlled reactive airways disease are not candidates for a β-blocker.[180]

Based on all these factors, there is no question that A.J. should be started on a β-blocker. Treatment with a β-blocker should be initiated at low doses, followed by gradual increments in dose every 2 weeks as tolerated. Transient bradycardia, hypotension, and fatigue are common during the first 24 to 48 hours when β-blockers are first started or during subsequent increases in dosage. Thus, patients should be monitored daily for changes in vital signs (pulse and BP) and symptoms during this uptitration period. Bradycardia, heart block, and hypotension can be asymptomatic and require no intervention other than instructing the patient not to arise too quickly from a lying position to avoid postural changes. If any of these complications is accompanied by dizziness, lightheadedness, or blurred vision, it may be necessary to reduce the dose of the β-blocker, the ACEI, or both or to slow the uptitration. In patients in whom benefits are especially apparent, but bradycardia or heart block is a concern, insertion of a pacemaker should be considered.

Because initiation of β-blocker therapy can also cause fluid retention, β-blockers should only be started or uptitrated when the patient is euvolemic. Patients should be instructed to weigh themselves daily and to adjust concomitantly administered diuretics as appropriate. Diuretic doses should be decreased temporarily if patients become hypotensive or their BUN begins to rise. Planned increments in the dose of a β-blocker should be delayed until any side effects observed with lower doses are tolerable or absent.

CASE 14-1, QUESTION 18: Metoprolol succinate (12.5 mg) is prescribed for A.J. Is this a good choice of agent and starting dose? What other similar drugs have been used to treat HF?

METOPROLOL AND BISOPROLOL

Several clinical trials substantiate the clinical benefits of metoprolol, a relatively selective β_1-receptor blocker, in HF.[181–184] By blocking β_1 receptors in the myocardium, HR, contractility, and CO are reduced at rest and during exercise, without a compensatory increase in peripheral vascular resistance. The relative sparing of β_2-receptors in

the peripheral vasculature and lungs reduces vasoconstrictive and bronchospastic complications.

Effect of Metoprolol CR/XL in Chronic Heart Failure: **Me**toprolol CR/XL **R**andomized **I**ntervention **T**rial in Congestive **H**eart **F**ailure (MERIT-HF) showed a 35% reduction in all-cause mortality with sustained-release metoprolol succinate.[184] In this trial, 3991 patients, most of whom had NYHA class II or III HF, were randomly assigned to receive metoprolol succinate controlled-release (CR)/XL formulations or placebo. The starting dose of metoprolol was 12.5 to 25 mg/day, which was gradually increased every 2 weeks to the target dose of 200 mg/day. Conventional therapy with diuretics, ACEIs, and digoxin was continued. At the end of the trial, 64% of subjects assigned to the active drug had reached the target dose. Although the number of subjects was too small to detect a statistical difference, patients with severe (class IV) HF seemed to benefit as well. Up to 15% of subjects had clinical worsening of HF, even at low metoprolol doses.

Positive results have also been seen with another relatively β_1-selective drug, bisoprolol fumarate.[185,186] In the first *C*ardiac *I*nsufficiency *BI*soprolol *S*tudy (CIBIS I), 641 subjects with moderate-to- severe HF were randomly assigned to placebo or bisoprolol (starting dose, 1.25 mg/day; maximal dose, 5 mg/day) added to conventional therapy for an average of 23 months.[185] A statistically significant reduction in HF-associated hospitalization with the active drug and an insignificant trend toward reduced mortality were noted. In the larger second *C*ardiac *I*nsufficiency *BI*soprolol *S*tudy (CIBIS II), reduction in both hospitalization and mortality in the bisoprolol-treated group was significant.[186] A total of 2647 patients were included in the second trial, and doses were increased to as high as 10 mg/day. The study was stopped prematurely because of a 34% reduction in total mortality with bisoprolol. As in the MERIT-HF study, the number of patients with severe (class IV) HF was inadequate to determine the value of β-blocker therapy in this population.

Two dosage forms of metoprolol are marketed: metoprolol succinate XL and metoprolol tartrate immediate-release

formulations. Only metoprolol succinate is approved for HF in the United States. It is indicated for patients with mild-to-moderate (NYHA class II or III) HFrEF. The starting dose of 12.5 mg of metoprolol succinate prescribed for A.J. is consistent with the clinical trials and manufacturer's labeling. If the initial dose is tolerated, the dose can be doubled to 25 mg daily for an additional 2 to 4 weeks. The final target dose is 200 mg daily either as 100 mg bid or 200 mg once daily.

When choosing among the various formulations of metoprolol, pharmacokinetic and bioavailability differences should be considered.[181,182] Metoprolol succinate is available as 25-, 50-, 100-, and 200-mg tablets. Each tablet is slowly released at a constant rate for 20 hours and provides β-blockade for 24 hours. The XL formulation retains its release characteristics even if the scored tablet is divided in half, but it should not be crushed or chewed. Having the ability to split tablets is useful in the titration of metoprolol succinate when the goal is to reach target doses and sometimes patients require slower titrations.

Metoprolol has several metabolic routes of elimination that can affect dosing and drug interactions. The major routes of elimination are via α-hydroxylation, *O*-demethylation, and *N*-dealkylation.[181,182] A smaller portion is metabolized by cytochrome P450 2D6 (CYP2D6), and drugs that inhibit the metabolism of that isoenzyme may affect the drug's plasma levels. Approximately 10% of patients are poor metabolizers, resulting in higher drug plasma concentrations in these patients.

A.J. should be advised that the beneficial clinical response to metoprolol is usually delayed and may require 2 to 3 months to become apparent. Even if symptoms do not abate, long-term treatment should be maintained to reduce the risk of major clinical events. Abrupt withdrawal of treatment with a β-blocker can lead to clinical deterioration and should be avoided.[187]

Bisoprolol is FDA approved for treatment of HFrEF. Dosage size limitations, however, limit the clinical use of this drug. For example, the starting dose of bisoprolol is 1.25 mg/day, whereas the smallest

commercially available dose in the United States is a 5-mg scored tablet. Attempting to break the tablet into quarters is not practical.

CARVEDILOL

Carvedilol is a β-blocker with some blocking activity.[188] It is also theorized to possess antioxidant effects, which can protect against loss of cardiac myocytes and scavenge oxygen free radicals that are thought to potentiate myocardial necrosis. The correlation of these findings with clinical outcome is unknown.

Two pivotal studies support the use of carvedilol. The first was the U.S. Carvedilol Heart Failure Study.[189–193] Subjects were almost equally divided between NYHA classes II and III HF, and all had an EF of ≤35% despite diuretics, digoxin, and an ACEI. Subjects were stratified based on the severity of their HF and then randomly assigned to receive either placebo or carvedilol. The maximal dose given was 50 mg twice daily. During an average of 6.5 months, the mortality rate in the placebo group was 7.8% compared with 3.2% in the active treatment group, a statistically significant 65% risk reduction. The patients treated with carvedilol also had fewer HF-related hospitalizations. The most common side effect with carvedilol was dizziness.

In the Australia/New Zealand Carvedilol Study, 415 patients with chronic, stable HF were randomly assigned to receive placebo or carvedilol.[194] Those with severe symptoms were excluded. Maintenance doses in subjects randomly assigned to receive carvedilol ranged from 6.25 to 25 mg twice daily with an average follow-up of 19 months. After 12 months, EF had increased by 5.3%, and heart size was reduced in the carvedilol group. However, no differences between groups were found in treadmill exercise time, change in NYHA classification, or HF symptom scores. Most (58% in both groups) had neither improvement nor worsening of symptoms. The frequency of episodes of worsening HF was similar in the two groups. Total deaths in the carvedilol group were less than that in the placebo group, but most of the difference in mortality was attributed to non-CV deaths. There were 68% fewer hospital admissions for HF

in the carvedilol group than that for the placebo group. Overall, these findings could be interpreted as evidence for safety with either no overall benefit or a modest improvement with carvedilol.

The starting dose of carvedilol is 3.125 mg twice daily, with a doubling of the dose every 2 weeks or as tolerated up to a maximum of 25 mg twice daily in patients weighing <187.39 pounds (<85 kg) and 50 mg twice daily in larger patients. Hypotension, bradycardia, fluid retention, and worsening HF symptoms can occur in the first few weeks of therapy, necessitating additional diuretics, a reduction in dose, or discontinuation of carvedilol. Taking carvedilol with food slows the rate of absorption and reduces the incidence of orthostatic hypotension, which occurs in up to 10% of patients taking the drug. As with any β-blocker, carvedilol is not recommended for use in patients with asthma or poorly controlled diabetes.

Because carvedilol is metabolized by the CYP2D6 enzyme system, several potential drug interactions should be considered.[188,195] The best-documented ones are inhibition of metabolism by cimetidine and decreased carvedilol serum concentrations when taken with rifampin. Known inhibitors of CYP2D6 (quinidine, fluoxetine, paroxetine, and propafenone) might increase the risk of toxicity (especially hypotension). Carvedilol has been reported to increase serum digoxin levels by 15% by an unknown mechanism. Other sources of intrasubject variability in carvedilol response may be caused by differences in the extent or rate or absorption, stereospecific metabolism of the two isomers of the drug (carvedilol is a racemic mixture of *S*[−] and *R*[+] isomers), and impaired metabolism in the 10% of the population who lack CYP2D6 activity.[195]

CHOICE OF A-BLOCKER: METOPROLOL VERSUS CARVEDILOL

Case 14-1, Question 19: Would carvedilol be a better alternative than metoprolol for A.J.? What would be an appropriate dose and dosing schedule?

No consensus exists regarding the relative superiority of one β-blocker versus another. The additional α_1-blockade and antioxidant properties of carvedilol provide a theoretical basis for selecting carvedilol instead of metoprolol succinate or bisoprolol.

The *C*arvedilol *O*r *M*etoprolol *E*uropean *T*rial (COMET) was a multicenter, double-blind trial, where 3029 patients with NYHA classes II through IV HF and EF <35% were randomly assigned to receive either carvedilol (target dose, 25 mg bid) or metoprolol tartrate (target dose, 50 mg bid). Diuretics and ACEIs were continued in all subjects if tolerated. All-cause mortality was 34% for carvedilol compared with 40% with metoprolol (P = .0017).[196] The composite end point of mortality or all-cause hospital admissions were not significantly different. One major criticism of this study was the use of metoprolol tartrate instead of metoprolol succinate. Comparable doses between the two study groups have been questioned because the target dose of carvedilol was 25 mg twice daily compared with the target dose of metoprolol tartrate being 50 mg twice daily. Also, the trial used RHR to determine comparable β-blockade among study groups rather than HR response to exercise. Exercise-induced HR changes are considered a better indicator of β-blockade.

Side effects and patient tolerability are similar among β-blockers in most trials. One investigator observed that carvedilol caused more hypotension and dizziness than did metoprolol or bisoprolol, possibly owing to α_1-blockade or more rapid absorption.[197] Thus, metoprolol or bisoprolol may be preferred in patients with hypotension or dizziness. Conversely, carvedilol may be preferred in patients with inadequately controlled HTN.

Whether carvedilol is a better choice for A.J. cannot be definitely answered. A starting dosage of 3.125 mg twice daily of carvedilol could be used in place of metoprolol succinate. Both drugs are generic, although the metoprolol sustained-release product is more expensive. A.J.’s provider decided to continue metoprolol and reserve use of carvedilol if he has difficulty tolerating metoprolol.

a-Blockers in Severe Heart Failure

Case 14-1, Question 20: The original clinical trials of β-blockers excluded patients with severe (NYHA class IV) HF at the time of randomization. For this reason, the FDA limited the original approval of carvedilol for use in NYHA classes II and III HF. Likewise, the ACC/AHA guidelines strongly support the use of β-blockers in NYHA classes II and III HF, but are less definitive about severe HF. If A.J. presented with NYHA class IV HF, what evidence supports or refutes the use of β-blockers in A.J.?

The carvedilol prospective randomized cumulative survival study (COPERNICUS)[198] study demonstrated clear benefit of carvedilol in patients with severe HF. COPERNICUS was a double-blind, placebo-controlled trial assessing the clinical benefits and risks of carvedilol in patients with advanced HF (NYHA class IIIB or IV).[198] Subjects who required intensive care, had significant fluid retention, were hypotensive, had evidence of renal insufficiency, or were receiving IV vasodilators or positive inotropic drugs were excluded. The starting dose of carvedilol was 3.125 mg twice daily and increased every 2 weeks to a target dose of 25 mg twice daily. Of those in the carvedilol group, 65% achieved the target dose, with the mean dose being 37 mg at the end of the first 4 months of the trial. The trial was discontinued prematurely after an average patient follow-up of 10.4 months because of a significant survival benefit from carvedilol.

The beta-blocker evaluation of survival trial (BEST) investigators failed to demonstrate that bucindolol, a nonselective β-blocker with vasodilator properties, improved overall survival in patients with NYHA classes III and IV HF.[199] They randomly assigned 2708 patients to receive either bucindolol or placebo. Although the active drug yielded a significant decrease in NE levels and improvement in LV function, the study was stopped prematurely because of the low probability of showing any significant CV mortality benefit compared with placebo. A possible explanation is that bucindolol has intrinsic sympathomimetic activity that may counteract some of the benefits of β-blockade. Moreover, subgroup analysis suggested that Black

patients might have fared worse with bucindolol, raising concerns that β-blockers may not be effective therapy for Black patients with advanced HF (see Case 14-4, Question 2, for further discussion of possible racial differences in drug response). Bucindolol has not been approved by the FDA.

Controversy still remains about the safe and effective use of β-blockers in class IV HF. There are data to support the safe and effective use of carvedilol. Clinically, the use of β-blockers is generally continued unless the patient requires inotropic therapy or if a dose increase of the β-blockers caused the ADHF episode. If the dose titration resulted in ADHF, then most patients should receive their previous β-blocker dose, but some may require acutely holding the β-blockers and reinitiating once stabilized.

CASE 14-1, QUESTION 21: When is it appropriate to add ivabradine in HFrEF?

A meta-analysis[200] of patients with HFrEF treated with β-blockers demonstrated that the degree of HR reduction correlated with improved mortality. We also know that initiation or titration of β-blockers can be challenging because of their side effects or preexisting contraindications. Evidence also supports that for every 5 bpm reduction in HR achieved, an 18% reduction in all-cause mortality is observed. Additional HR reducing therapies in the treatment of HF, with I_f channel inhibition, were tested in clinical trials. The first of these was the mor**B**idity-mortality **E**v**A**l**U**a**T**ion of the **IF** inhibitor ivabradine in patients with coronary disease and left-ventric**UL**ar dysfunction (BEAUTIFUL) trial.[201] The BEAUTIFUL study highlighted that in certain subgroups with elevated HR, a signal for reduce admission for acute MI by 36% (fatal and nonfatal; P = .001); reduce composite admission for acute MI or unstable angina by 22% (P = .023) was observed. These findings led to trials for assessing the true effects of ivabradine in the subgroup of patients with HFrEF and HR of at least 70 bpm, the **S**ystolic **H**eart failure treatment with the **IF** inhibitor ivabradine **T**rial (SHIFT).[68]

The SHIFT tested the effect of ivabradine as add-on to standard treatment with ACEIs and β-blockers in patients with chronic HF in sinus rhythm. The SHIFT trial randomized 6558 patients with symptomatic HF to ivabradine versus placebo. Patients had an EF ≤35%, normal sinus rhythm with an HR of ≥70 bpm, NYHA FC II to IV symptoms and at least one hospitalization for HF within the previous year. In addition to background treatment, which generally included a β-blocker (89%), ACEI, and/or an ARB (93%), patients received either ivabradine at 5 mg twice daily with an increase to 7.5 mg twice daily to maintain an RHR between 50 and 60 bpm, or placebo. During a median 23 months of follow-up, patients in the ivabradine group had an 18% decrease in risk of CV death or hospitalization (HR, 0.82; *P* < .0001). Ivabradine significantly reduced the risk of hospitalization for worsening HF and death due to HF but did not have a significant effect on all-cause mortality 503 (16%) versus 552 (17%); (HR 0.90, 95% CI 0.80–1.02; *P* = .092). Ivabradine was well tolerated with relatively few adverse events, although significantly more than that with placebo. The most common adverse events were bradycardia, AF, and transient blurring of vision. Overall, ~70% of the patients in the ivabradine arm were at target dose (7.5 mg bid), and <10% had to be downtitrated to the lowest dosage (2.5 mg bid). Patients with contraindications to β-blockers, β-blocker doses of <50% of GDMT targets, and an RHR of 77 bpm benefited the most.

Ivabradine reduces HR without effects on inotropy, BP, and vascular resistance. Evidence suggests that in patients with HFrEF who cannot tolerate β-blockers because of adverse effects and in whom HRs remain elevated, the addition of ivabradine can be considered to reduce HR to <70 bpm. However, the trial results cannot be generalized to the overall HF population, particularly the elderly, with permanent AF or HFpEF. Ivabradine is best viewed by clinicians as a second-line drug for systolic dysfunction.

Ivabradine is initiated at 5 mg twice daily and titrated to 7.5 mg twice daily based on efficacy and tolerability, with a goal HR of 51 to 60 bpm. If, after initiation, there is an observed RHR <60 bpm, the dose is decreased to 2.5 mg twice per day. Ingestion with food is

recommended to increase systemic absorption by 20% to 30%. Ivabradine is metabolized by CYP3A4 enzymes in the liver and it is recommended to avoid concurrent administration with potent inhibitors of CYP3A4. In patients with mild or moderate hepatic impairment (Child–Pugh A or B), no dose adjustments are required. Ivabradine use is contraindicated in those with severe (Child–Pugh C) hepatic impairment. No dose adjustment is required for renal impairment where the CrCl is between 15 and 60 mL/minute. There are currently no data available for use in patients with CrCl <15 mL/minute.[45]

Angiotensin Receptor–Neprilysin Inhibitor

Case 14-1, Question 22: A.J. presents to the HF clinic for a follow-up visit after a recent hospitalization. His HF medications include lisinopril 20 mg daily, carvedilol 12.5 mg twice daily, and spironolactone 25 mg daily. His laboratory values are Na 141 mEq/L, K 4.1 mEq/L, SCr 1.1 mg/dL, and NT-proBNP 653 pg/mL. He denies PND, weight gain, and dizziness (SBP 138/85 mm Hg, HR 60 bpm) but reports getting short of breath while performing yard work. He is euvolemic on examination and a repeat echo shows an LVEF 30% to 35%, which has not changed from last year. The cardiologist wants to switch A.J. to sacubitril/valsartan for additional mortality benefits. What is the evidence to support this change in therapy?

The combination of sacubitril and valsartan was studied in the PARADIGM-HF[62] trial as an alternative to ACEI therapy. This was a multicenter, randomized, double-blind trial (*N* = 8422), and consisted of three phases: the screening period, a single-blind run-in period during which all patients received enalapril, and was followed by a single-blind run-in period with all patients receiving ARNI to ensure tolerability of the study drugs at target doses. Patients who tolerated the two medications were then randomized in a 1:1 ratio to either enalapril 10 mg twice daily) or ARNI (200 mg twice daily). Subjects who had LVEF <35% and elevated BNP levels were included, almost all of whom were in NYHA FC classes II to III, ACEI or ARB therapy with stable doses in the prior 4 weeks to randomization (equivalent

to enalapril ≥10 mg/day), and stable doses of β-blockers. Patients were excluded if SBP <100 mm Hg at screening or <95 mm Hg at randomization, estimated glomerular filtration rate (eGFR) <30 mL/minute/1.73 m^2, potassium >5.2 mmol/L at screening or >5.4 mmol/L at randomization, and history of angioedema. At 3.5 years of follow-up, there was a significant reduction in the primary outcome of CV death or HF hospitalization in the S/V group (21.8%) versus the enalapril group (26.5%) (HR 0.80; 95% CI 0.73–0.87; *P* < .001; NNT 21). Patients receiving sacubitril/valsartan had lower rates of hyperkalemia, renal dysfunction, and cough but higher rates of hypotension (14.0% vs 9.2%; *P* < .001; NNT 21). Overall, fewer patients on sacubitril/valsartan stopped their study medication because of an adverse event and required treatment intensification and use of advanced therapies (inotropes, assist devices, cardiac transplantation) when compared with enalapril.

The finding that sacubitril/valsartan had a superior effect on CV mortality compared to enalapril lends support that an ARNI could replace ACEIs and ARBs in patients with HFrEF who remain symptomatic despite being on optimal GDMT. Even though ARNI met the criteria for clinical superiority when compared with conventional therapy, the benefits have to be weighed against the side effect profile. In clinical practice, the frequency of the side effects (hypotension, angioedema) may be more pronounced because of a patient population with more complications.

A.J. is currently on a target dose of lisinopril and a moderate dose of metoprolol succinate. He reports SOB with minimal activity, and weight is stable and euvolemic on physical exam. He does not report any symptomatic hypotension and has adequate SBP, 138/85, K^+ is <5.0, and SCr is stable, and EF has not improved despite being on optimal GDMT. Guidelines recommend replacing an ACEI or ARB with an ARNI in patients with HFrEF or NYHA class II or III who tolerate an ACEI/ARB. A.J. fits the guideline criteria to switch to ARNI. Dose selection should be based on patient-specific factors such as SBP, renal function, age, hepatic function, and current ACEI/ARB dose. Because all labs are within normal limits and A.J. is on a high dose of lisinopril, he can be safely switched to ARNI 49/51

mg twice daily. When making the transition from lisinopril, a 36-hour washout period between the last dose of lisinopril and the first dose of ARNI should be observed to avoid the risk of angioedema. Renal function and SBP should be monitored in 2 to 4 weeks to assess tolerability and dose uptitrated to the target dose of 97/103 twice daily if appropriate (**Table 14-12**).

Table 14-12
ARNI Dosing

Population	Initial Dose	Comments
ACEI/ARB naive	ARNI 24/26 twice daily	Allow 36-hour washout if on an ACEI. Also if SBP <100 mm Hg, initiate low dose. If patient tolerates, make every effort to increase to target dose 97/103 mg.
[a]Low- or medium-dose ACEI/ARB		
eGFr <30 mL/minute		
Elderly ≥75 years		
Hepatic impairment (Child–Pugh B classification)		
High-dose[b] ACEI/ARB	ARNI 49/51 twice daily	Evaluate SBP and rule out symptomatic hypotension before initiation.

ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker; ARNI, angiotensin receptor–neprilysin inhibitor; eGFR, estimated glomerular filtration rate; SBP, systolic blood pressure.

[a]Low/medium dose ≤ enalapril 10 mg or equivalent dose of another ACEI.

[b]High dose > enalapril 10 mg or equivalent dose of another ACEI.

[a]Low/medium dose ≤ valsartan 160 mg daily or equivalent dose of another ARB.

[b]High dose > valsartan 160 mg daily or equivalent dose of another ARB.

Yancy CW, Januzzi JL, Allen LA, et al. 2017 ACC expert consensus decision pathway for optimization of heart failure treatment: answers to 10 pivotal issues about heart failure with reduced ejection fraction: a report of the American College of Cardiology task force on expert consensus decision pathways. *J Am Coll Cardiol*. 2018;71(2):201–230.

CASE 14-2

Question 1: S.P. is a 66-year-old male with an EF <35% and is scheduled with a pharmacy HF titration clinic. His HF medications include lisinopril 10 mg daily and metoprolol succinate 150 mg daily. He was recently initiated on ARNI 24/26 twice daily. Vitals and labs include BP 118/89 mm Hg, HR 70 bpm, SCr 1.2 mg/dL, and K 4.4 mEq/L.

What steps will you take to safely titrate the ARNI?

The common barriers to initiation and titration of GDMT are renal insufficiency and/or hyperkalemia and symptomatic hypotension. Clinical assessment of patient-specific factors is necessary to successfully titrate medications to target doses. A study was conducted to assess the safety and tolerability of initiating and uptitrating ARNI in real-world patients with HFrEF. TITRATION (Safety and Tolerability of Initiating LCZ696 in Heart Failure Patients) was a randomized,[202] double-blind study that assessed the safety and tolerability of initiating and uptitrating ARNI in a 3-week (condensed) regimen, versus a 6-week (conservative) regimen in patients with HFrEF (EF ≤35). Primary end points were the proportion of patients experiencing prespecified adverse events (symptomatic hypotension, hyperkalemia, renal dysfunction, angioedema) and laboratory outcomes including SBP <95 mm Hg, and a doubling of SCr from baseline. Secondary end points included the number of patients achieving the target dose without any downtitration or interruption over 12 weeks (defined as treatment success) and tolerating the target dose for at least 2 weeks. After 5 days of run-in with sacubitril/valsartan, patients were randomized to sacubitril/valsartan titrated up to 200 mg twice daily (50–200 mg twice daily) over 3 weeks or 6 weeks. Randomized patients were also stratified based on Renin-Angiotensin-Aldosterone System inhibitor (RAASi) use at screening, with the high-stratum group using >10 mg total daily dose of enalapril, >160 mg of valsartan, or equivalent doses of other ARBs/ACEIs. There were no differences in the primary end points between groups. Treatment success was achieved in 78% and 84% of patients in the condensed and conservative regimens, respectively (P = .07). At least 76% of

randomized patients achieved and maintained the target dose of ARNI 200 mg bid, regardless of the uptitration regimen. In the prestudy low-dose group, treatment success was achieved with the conservative approach (low RAASi, 73.6% for the condensed group, and 84.9% of the conservative group [*P* = .03]). High prestudy RAASi dose was associated with similar treatment success in both groups (82.6% vs 83.8%, respectively). Overall, there was no difference between the groups for tolerability. There was also no difference between the groups for tolerability based on high or low RAASi use. Furthermore, the target dose was achieved even in patients requiring dose interruptions. This study supports that ARNI can be safely titrated to target doses in the majority of patients in clinical practice irrespective of the speed of titration. Study limitations included the open-label design of the run-in period, the limited number of inpatients (around 11%) and those naive to ACEI/ARB at baseline (around 7%), and the absence of an active comparator arm. Nevertheless, a gradual titration should be implemented in patients who were previously receiving low doses of ACEI/ARB with diligent follow-up to attain target doses.

Given that S.P. was on a low dose of lisinopril, and his SBP is at the lower end, his dose can be titrated to target or maximum tolerated dose over 6 weeks with a 2- to 3-week follow-up after each titration to assess tolerability.

Aldosterone Antagonists

CASE 14-3

Question 1: B.D. is a 65-year-old Caucasian male with an LVEF of <25% who presents to the HF clinic today for follow-up of his recent HF hospitalization. His BP is 120/85 mm Hg, and his pulse is 70 bpm. His current medications include lisinopril 10 mg daily, metoprolol succinate 150 mg daily, and furosemide 20 mg daily. You have reviewed his chart and noted that these are the maximal tolerated doses of lisinopril and metoprolol owing to dizziness and near syncope with higher doses. Today, his laboratory results show that his SCr is 0.9 mg/dL, and his potassium level is 3.5 mEq/L.

Is this patient a candidate for AA therapy?

Aldosterone contributes to HF through the increased retention of sodium and water and contributes to the depletion of potassium. Likewise, the diuretic and potassium-sparing actions of spironolactone are attributed to inhibition of aldosterone.[203] At one time, it was believed that optimal doses of ACEIs fully suppressed the production of aldosterone. It is now recognized that aldosterone levels can remain elevated through a combination of nonadrenal production and reduced hepatic clearance. In addition, it has become clear that both angiotensin II and aldosterone have other negative effects on the CV system, including myocardial and vascular fibrosis, direct vascular damage, endothelial dysfunction, oxidative stress, and prevention of NE uptake by the myocardium.[22,204] This led the RALES investigators to test the hypothesis that low doses of spironolactone might impart a cardioprotective effect in patients with severe HF independent of diuresis or potassium retention. In this trial, 1663 patients with a history of NYHA class IV HF were randomly assigned to receive either spironolactone 25 mg or placebo. The dose of spironolactone could be increased to 50 mg if HF worsened without evidence of hyperkalemia.

The study was discontinued prematurely after a mean follow-up of 24 months when a significant reduction in mortality was observed in the spironolactone group. Hospitalization rates were lower in the patients treated with spironolactone. Hyperkalemia developed in 2% of the patients on spironolactone and 1% of those on placebo. Gynecomastia was reported in 10% of males treated with spironolactone compared with only 1% of those receiving placebo.

In 2011, the *E*plerenone in *M*ild *P*atients *H*ospitalization *A*nd *S*urv*I*val *S*tudy in *H*eart *F*ailure (EMPHASIS-HF) was published. This study evaluated eplerenone in patients with NYHA class II HF and an EF of <35%.[59] In EMPHASIS-HF, subjects were randomly assigned to receive either eplerenone or placebo. The primary outcome of the trial was CV death or HF hospitalization. During a median follow-up of 21 months, 18.3% of patients treated with eplerenone versus 25.9% of patients on placebo had a primary

outcome event ($P < .001$). This study further supported the role of AAs in HFrEF and expanded the known effectiveness to NYHA class II HF patients.

B.D. has NYHA class II HF based on his current symptom control and fits the profile of the subjects in the EMPHASIS-HF study, although he is on a low dose of ACEI. Starting B.D. on an AA is appropriate because of his relative intolerance to increasing the dose of ACEI and β-blocker. An initial spironolactone dose of 25 mg/day should be chosen for B.D. based on the dose studied in the RALES trial. Spironolactone is chosen based on the likely class effects of AAs in HF treatment and the lower cost compared with eplerenone. This dose is safe based on his current potassium level of 3.5 mEq/L and SCr of 0.9 mg/dL. He will need to be followed up to determine his potassium and SCr 2 weeks after initiation. Specific monitoring parameters for the management of hyperkalemia in patients treated with AAs can be found in **Table 14-11**.

CASE 14-3, QUESTION 2: Because BD was started on spironolactone, his K has increased to 5.0meq/L and Scr is 0.9mg/dL. The medical attending is asking you if BD should be started on a potassium binder to manage hyperkalemia?

BD is not yet a candidate for potassium binders. All causes of hyperkalemia should be evaluated and potassium should be monitored and if K levels continue to rise then the dose of spironolactone should be reduced to 12.5 mg daily. One of the barriers to optimizing RAASi is the development of hyperkalemia. In clinical practice, an increase in serum potassium levels often leads to either RAASi dose reduction or discontinuation of therapy. Clinical trials have shown a significant reduction in mortality/ morbidity benefits when patients receive target doses of RAASi therapy. Furthermore, guidelines also recommend diligent monitoring of potassium and renal function when initiating or titrating RAASi. When prescribing AA therapy, a more stringent monitoring is mandated. Consequentially AAs are underprescribed despite class 1A recommendations. In the AA landmark trials, the incidence of

hyperkalemia (K^+ >5.5 mmol/L) was low without any hyperkalemia-associated fatal events. In addition, post hoc analysis of the RALES and EMPHASIS-HF trials[58,59] have shown persistent benefits despite the development of moderate hyperkalemia (5.5–6.0 mmol/L) during treatment. Nevertheless, hyperkalemia continues to be a challenge in the real world, and clinicians are often hesitant to initiate or titrate RAASi therapy. In recent years, two potassium binders, patiromer and sodium zirconium cyclosilicate (SZC), have been approved by the FDA to facilitate continuation of RAASi therapy. Both agents remove potassium by exchanging cations for potassium in the gastrointestinal tract, binding potassium, and increasing its fecal excretion.

Three main clinical trials[205–207] have collectively demonstrated patiromer to be effective in decreasing serum potassium, preventing recurrence of hyperkalemia, and reducing RAASi discontinuation. Similarly, the HARMONIZE (Hyperkalemia Randomized Intervention Multidose ZS-9 Maintenance) trial showed a dose-dependent potassium-lowering effect of SZC.[208]

SZC acts within 1 hour of administration by permanently removing excess potassium in the gastrointestinal tract, whereas patiromer decreases potassium levels at 7 hours after administration; levels continue to decrease for at least 48 hours if treatment is continued and remain stable for 24 hours after administration of the last dose. Both these agents increase the risk of hypokalemia and patiromer increases rates of hypomagnesemia, whereas SZC is associated with increased edema in patients with HF. Patiromer can reduce the absorption of other oral medications such as ciprofloxacin, and a 3-hour separation would avoid potential drug–drug interactions. SZC can transiently increase gastric pH and should be administered at least 2 hours after or before the concomitant drug that displays pH-dependent solubility.[209]

Potassium-binding agents can certainly help optimize RAASi therapy; however, there are still many unanswered questions, such as optimal time to initiate and discontinue these medications once hyperkalemia is resolved.

Digitalis Glycosides

Case 14-3, Question 3: B.D. has tolerated spironolactone 25 mg daily for 2 months. His laboratory test results today show that his potassium is 4.4 mEq/L and his SCr is 1.0 mg/dL. His BP is 124/82 mm Hg, and his pulse is 70 bpm. He has come to the clinic today for a follow-up appointment with his cardiologist who notes that B.D. has had four HF hospitalizations in the past year. B.D. also reports increased SOB, DOE, and PND, although his weight is stable and he takes all his medications as prescribed. The medical resident who is also staffing the clinic asks whether it would be appropriate to add digoxin to B.D.'s medical treatment of HF. He was told by a colleague that in clinical trials, digoxin reduced both HF symptoms and hospitalizations for HF. What would you recommend?

Debates raged for years about whether digitalis glycosides or vasodilators should be the drug(s) of first choice for treating HFrEF. By the time the first ACC/AHA guidelines were published, a clear consensus was evident. Vasodilators are first-line therapy, with digoxin being added for patients with supraventricular arrhythmias, failure to achieve symptomatic relief with vasodilators alone, or intolerable side effects from vasodilators. ACEIs are preferred compared to other vasodilators because of proven efficacy, convenience of dosing, and fewer side effects. By 1999, experts also recommended starting β-blocker therapy earlier in the treatment plan. Digoxin, however, continues to be widely debated.

CONTROVERSY ABOUT EFFICACY OF DIGOXIN

Correction of the underlying defect is a rational approach to the treatment of any disease. When considering HF solely as "pump failure" with a weakened myocardial muscle, digitalis is the logical choice to improve cardiac contractility, CO, and renal perfusion. If focusing on symptom relief and increased exercise tolerance as markers of benefit, digoxin is effective. Critics, however, raised concerns that symptom relief was less in patients with normal sinus rhythm than in those with supraventricular arrhythmias. The most vocal critics claimed that the risk of digitalis toxicity did not warrant using this class of drugs in patients with normal sinus rhythm.

Using multivariate analysis, one group of investigators concluded that a third heart sound (S_3 gallop rhythm), an enlarged heart, and a low EF best predict those patients with normal sinus rhythm who will derive a beneficial response from digoxin.[210] Several other meta-analyses and critical reviews of the literature concurred that digoxin therapy provides a beneficial effect, especially in patients with severe symptomatic ventricular systolic dysfunction.[211,212] However these opinions were based on historical data and when many current therapies were not available.

DIGOXIN WITHDRAWAL TRIALS

In 1993, two digoxin withdrawal trials, **P**rospective **R**andomized Study of Ventricular Failure and the Efficacy of Digoxin (PROVED)[213] and **R**andomized **A**ssessment of **D**igoxin on **I**nhibitors of the **AN**giotensin **C**onverting **E**nzyme (RADIANCE),[214] were published. Both attempted to determine whether patients with HF who were already treated with digoxin would show deterioration after discontinuation. In both studies, patients had documented HFrEF (LVEF <35%), mild-to-moderate symptoms, were in normal sinus rhythm, and stable for at least 3 months with treatment of a diuretic and digoxin (baseline digoxin level, 0.9–2.0 ng/mL). Patients in the RADIANCE trial were also stabilized on an ACEI in addition to the diuretic and digoxin.[214] A 12-week, double-blind, placebo-controlled treatment period followed initial stabilization in both studies. Patients in the active treatment groups continued digoxin at their previous dose. Those in the placebo groups were withdrawn from digoxin and given placebo.

In PROVED,[213] 42 subjects continued digoxin and 46 were given placebo. There were 29% treatment failures in the withdrawal group compared with 19% in those taking digoxin. Exercise tolerance worsened in more patients taking placebo. Those taking digoxin tended to maintain lower body weight and HR as well as higher EF. In the RADIANCE study, 85 subjects continued digoxin therapy, and 93 were switched to placebo.[214] During the 12-week follow-up period, 4.7% of the subjects taking digoxin experienced worsening

symptoms compared with 24.7% of the patients on placebo. More of the patients on placebo had worsening of EF and lower quality-of-life scores. When comparing the two trials directly, fewer patients deteriorated in both arms in the RADIANCE study. Whether this is attributed to a greater benefit from combining an ACEI with a diuretic compared with using a diuretic alone (as in PROVED) cannot be established.

These studies establish a beneficial effect of digoxin, even in those patients receiving concurrent ACEIs. At least two factors, however, limit extrapolation to all patients with HF. First, the investigators only assessed the value of therapy indirectly using a withdrawal design instead of initiating therapy in patients previously untreated with digoxin. Second, the patients had advanced disease as evidenced by NYHA class II or III symptoms despite triple-drug therapy. Thus, the benefit of digoxin as initial monotherapy in early disease remains an unanswered question.

EFFECT OF DIGOXIN ON MORTALITY

The seminal study to answer the question of whether treatment with digoxin improves survival in HF was the Digitalis Intervention Group (DIG) study.[215] In this study, 6800 patients with HF were randomly assigned to receive either digoxin or placebo. Eligibility requirements included an EF of ≤45% (mean, 28% in both groups), normal sinus rhythm, and clinical evidence of HF. Most subjects were in NYHA class II or III HF, although a small number of class I and class IV subjects were included. Concurrent therapies included diuretics, ACEIs, and nitrates. In both groups, 44% were taking digoxin before randomization. The starting digoxin dose (or placebo) was based on age, weight, and renal function, with subsequent adjustments made according to plasma level measurements. Approximately 70% of subjects in both groups ended up taking 0.25 mg/day. By 1 month, 88.3% of patients receiving digoxin had serum levels between 0.5 and 2.0 ng/mL, with a mean of 0.88 ng/mL. Patients were followed up for an average of 37 months.

For the primary outcome of total mortality from any cause, 34.8% of patients on digoxin and 35.1% of those on placebo died; corresponding CV deaths were 29.9% and 29.5%, respectively. Although neither of these differences is statistically significant, a trend was seen toward fewer HF-associated deaths and statistically fewer hospitalizations (risk ratio, 0.72) with digoxin. As would be expected, cases of suspected digoxin toxicity were greater in the active treatment group (11.9% vs 7.9%), but the incidence of true toxicity was low.

The DIG trial improves on the PROVED and RADIANCE trials because it added digoxin to other therapy as opposed to being a withdrawal study and also because of the larger population. However, because nearly all patients were receiving concurrent vasodilator therapy, the value of digoxin as monotherapy on mortality rates remains unanswered.

The ACC/AHA guidelines[2] indicate that patients with HF are unlikely to benefit from the addition of digoxin in stage A or stage B HF. In stage C patients, despite receiving optimal doses of ACEIs or β-blockers, digoxin may be beneficial to reduce HF hospitalizations.

Digoxin is prescribed frequently in patients with HF and concurrent AF, but β-blockers may be more effective in controlling the ventricular response, especially during exercise. Digoxin should be avoided if the patient has significant sinus or AV block unless the block is treated with a permanent pacemaker. Digoxin should be used cautiously in patients taking other drugs that can depress sinus or AV nodal function (amiodarone or β-blockers), although patients usually will tolerate this combination.

Despite being on maximal tolerated doses of lisinopril and metoprolol, B.D. continues to have HF symptoms. In patients with persistent HF symptoms, especially as with B.D. who also presents with an EF <25%, digoxin can be used as an additional agent. However, digoxin is not indicated as primary therapy for stabilization of patients with acutely decompensated HF. Such patients should first receive appropriate treatment, including IV medications.

SEX DIFFERENCES IN RESPONSE TO DIGOXIN

CASE 14-3, QUESTION 4: If B.D. had been a female, would it have made any difference in the consideration to prescribe digoxin?

The retrospective post hoc analysis of the DIG study data reported that the death rate was lower among females in the placebo group as compared to males (28.9% vs 36.9%; $P < .001$); however, this difference was not significant between females and males taking digoxin.[205] Females taking digoxin had a higher death rate than did females taking placebo (33.1% vs 28.9%), whereas death rates in males were similar in both groups. The authors speculate that a possible mechanism for the increased risk of death among females taking digoxin is an interaction between hormone replacement therapy and digoxin. Progesterone might increase serum digoxin levels by inhibiting P-glycoprotein (PGP), thus reducing digoxin renal tubular excretion. Consistent with this hypothesis, digoxin serum concentrations after 1 month of therapy were higher in females than in males. The study investigators, however, did not gather data on estrogen and hormone replacement therapy or consistently measure serum digoxin levels later in the trial. However, subsequent reanalysis[216] of the DIG data found lower serum concentrations (0.5–0.9 ng/mL) of digoxin associated with a decreased risk of hospitalizations and mortality in females. Serum concentrations >1.2 ng/mL were associated with higher risk of death when compared with the placebo group. Higher digoxin concentrations resulted in worse clinical outcomes both in males and females. Another analysis of patients treated with digoxin in the **S**tudies of **L**eft **V**entricular **D**ysfunction (SOLVD) trial failed to demonstrate a survival difference based on gender.[217] The available data suggest that serum digoxin concentrations in the range of 0.5 to 0.9 ng/mL are safe, improve LVEF, hemodynamics, and reduce hospitalizations irrespective of gender.

MAINTENANCE DOSE

Case 14-3, Question 5: What is the appropriate maintenance dose of digoxin for B.D.?

The usual maintenance doses of digoxin have traditionally ranged from 0.125 to 0.25 mg/day. With the increased emphasis on targeting lower serum concentrations (0.5–0.9 ng/mL), more patients are now empirically started at 0.125 mg/day. It is safer to start with a conservative dose and assess B.D.'s needs after 1 to 2 weeks.

In all cases, smaller doses of digoxin are given to patients with impaired excretion rates (those with renal failure, older patients) or small-framed individuals. For example, a patient who is totally anuric may receive only 0.0625 mg 3 or 4 days/week.

Loading doses of digoxin are rarely necessary. Slow initiation of therapy with maintenance doses of digoxin is the method of choice for ambulatory or nonacutely ill patients with normal renal function. Even in the acute care setting, no indication exists for loading doses of digoxin for HF alone. The exception might be if the patient has AF, and it is desired to control ventricular response as quickly as possible. Even then, alternative drugs are likely to be used (see Chapter 15, Cardiac Arrhythmias).

MONITORING PARAMETERS

Case 14-3, Question 6: How should B.D.'s digitalis therapy be monitored? How useful are digoxin serum levels in monitoring therapy?

No clear therapeutic end point exists for digoxin therapy. Nonspecific electrocardiographic (ECG) changes (ST depression, T-wave abnormalities, and shortening of the QT interval) correlate poorly with both toxic and therapeutic effects of the drug.[218,219] Although digoxin serum levels are readily available from most clinical laboratories, no "therapeutic level" and corresponding "toxic level" are clearly defined.

A few patients, especially if they are hypokalemic or hypomagnesemic, will manifest apparent signs of toxicity when

serum digoxin concentrations are <1 ng/mL. At the other extreme, some patients tolerate concentrations >2 ng/mL with no signs of overt toxicity. Such overlap between therapeutic concentrations and toxic levels limits the value of serum level monitoring. Serum levels can be used as a guide in confirming suspected toxicity or in explaining a poor therapeutic response, but clinical evaluation ultimately remains the best therapeutic guide.

Clinical evaluation

As with diuretic and vasodilator therapy, clinical monitoring is the key to evaluating adequacy of digitalis therapy. As B.D. begins to improve, he should have less dyspnea and report less PND, and a lower HR may be observed.

TREATMENT OF SUPRAVENTRICULAR ARRHYTHMIAS IN HEART FAILURE

Case 14-3, Question 7: B.D. did well for the next 6 months until he noted the onset of palpitations, which were diagnosed by ECG as AF. A month ago, his primary care physician increased his digoxin dose to 0.25 mg every day. How should we treat his AF?

Supraventricular arrhythmias are frequently encountered in HF because volume or pressure overload can cause atrial distension and irritability. Specifically, AF is present in 10% to 30% of patients with advanced HF,[98] contributing to reduced exercise capacity, increased risk of pulmonary or systemic emboli, and worse long-term prognosis. Drug therapy should be aimed at controlling ventricular rate and preventing thromboembolic events. Cardioversion to normal sinus rhythm in patients with low EF and dilated cardiomyopathy is often unsuccessful.

Digoxin slows the ventricular response associated with AF and is a logical choice in patients with concurrent HFrEF. A potential limiting factor is that digoxin's AV-blocking properties are most evident at rest and are less effective during exercise. Hence, digoxin may be

ineffective at controlling exercise-induced tachycardia that limits the patient's functional capacity. β-Blockers are more effective than is digoxin during exercise.[220–222] If digoxin, β-blockers, or both are ineffective, amiodarone is another useful alternative. Verapamil and diltiazem are not appropriate choices for rate control in patients with HFrEF because of their negative inotropic effects.

Some studies suggest that AF is an independent predictor of mortality in patients with HF, and restoration of sinus rhythm may reduce mortality and prevent recurrences. Most patients who are electrically cardioverted revert to AF in a short time. In CHF-STAT (Congestive Heart Failure: Survival Trial of Antiarrhythmic Therapy),[223] a subset of patients who were converted to normal sinus rhythm with amiodarone treatment had significantly lower mortality than did those who remained in AF. Similar results were observed in a substudy of the DIAMOND (*D*anish *I*nvestigations of *A*rrhythmia and *M*ortality *ON D*ofetilide) trial,[224] in which patients with HF having AF treated with dofetilide had significantly improved survival if the sinus rhythm was maintained. However, AF-CHF (Atrial Fibrillation in Congestive Heart Failure)[225] showed no mortality or morbidity benefits of rhythm control compared with rate control. The lack of mortality benefits seen in the AF-CHF might be explained by the high frequency of β-blocker use (88%). Antiarrhythmic agents are frequently unsuccessful in maintaining sinus rhythm.[223] Patients who benefit the most from conversion to sinus rhythm are the hemodynamically compromised. Maintaining sinus rhythm can potentially improve their quality of life.

The use of most antiarrhythmic agents, except amiodarone and dofetilide, is associated with worse prognosis because of proarrhythmic or negative inotropic effects and should be avoided in patients with HF. Although amiodarone and dofetilide do not increase mortality in patients with HF, they are associated with increased hospitalizations.[226] Current treatment guidelines do not support the routine use of anticoagulants in HF unless patients have concomitant AF or evidence of active thrombus. Finally, AV nodal ablation may be needed if tachycardia or bothersome symptoms persist despite aggressive pharmacologic intervention.

B.D. experienced AF while already taking a relatively high dose of digoxin (0.25 mg/day) and metoprolol. If his AF-associated palpitations persist, amiodarone should be started (see Chapter 15, Cardiac Arrhythmias). Amiodarone is a PGP inhibitor. The net effect of inhibition of gut PGP by amiodarone is increased bioavailability of digoxin. B.D.'s digoxin dose will need to be lowered by ~50% if amiodarone is started.[219,227] If digoxin is continued, serum levels should be closely monitored, and patients observed for clinical evidence of toxicity.

DIGOXIN DRUG INTERACTIONS

Case 14-3, Question 8: What are the other potential drug interactions with digoxin?

Two reviews of cardiac glycoside drug interactions have been compiled.[228,229] Since publication of these early reviews, a greater understanding of PGP-mediated drug interactions has evolved.[227,230] A brief summary of all digoxin interactions is found in **Table 14-13**. Drugs recently recognized as raising digoxin serum concentrations through PGP inhibition include atorvastatin,[231] CCBs (especially verapamil and diltiazem),[232] erythromycin and clarithromycin,[233,234] and cyclosporine. Conversely, rifampin[194] and St. John's wort[235] reduce oral digoxin bioavailability and serum concentrations via induction of intestinal PGP.

Table 14-13
Digoxin Drug Interactions

Drug	Effect
Drugs Lowering Serum Digoxin Concentration	
Rifampin[194]	Probable induction of intestinal P-glycoprotein causing ↓bioavailability
	↓Serum concentration after oral, but not IV digoxin. No change in digoxin renal clearance or half-life
St. John's wort[235]	Possible induction of P-glycoprotein (33%

	reduction in digoxin trough concentrations)[322]
Sulfasalazine doses >2 g/day	Malabsorption of digoxin (decrease AUC of digoxin by 24%)[322]
Drugs Raising Serum Digoxin Concentration	
Amiodarone[219,227]	↑Serum digoxin levels inhibit intestinal P-glycoprotein (70% in 1 day)[322]
Atorvastatin[229]	20% increase in serum digoxin concentration with 80-mg dose, minimal effect with 20-mg dose. Speculated to inhibit intestinal P-glycoprotein, but not proven
Calcium channel blockers[219,227,232]	Inhibition of P-glycoprotein. Best documented with verapamil (70%–80%).[323] Diltiazem increases digoxin concentrations by 50% in some patients.[323]
Clarithromycin[233,322]	Inhibition of P-glycoprotein, decreased digoxin renal clearance. Digoxin clearance may be reduced by 60%, and plasma concentrations may increase by twofold.[322]
Cyclosporine[219,227]	Inhibition of P-glycoprotein, decreased digoxin renal clearance
Erythromycin	↑Bioavailability in persons who normally metabolize digoxin in intestinal tract. May also inhibit P-glycoprotein in the gut. Digoxin concentrations may increase by 100% in some cases.[322]
Itraconazole[324]	↑Serum digoxin levels by unknown mechanism. In one study, the AUC for digoxin was increased by 50% and renal elimination was decreased by 20%.[322]
Propafenone[212,325]	Inhibition of P-glycoprotein. Increases digoxin concentrations by 30%–60%[322]
Quinidine[219,227,228,230,326–330] (usually doses >500 mg/day may increase digoxin serum concentrations)	Inhibition of P-glycoprotein, decreased digoxin renal clearance, and increased bioavailability. Increases 25%–100% digoxin concentrations[322]

References[219,227,229] include a discussion of many of these interactions that do not include a specific reference citation.

AUC, area under the curve; IV, intravenous.

DIGITALIS TOXICITY

Signs and symptoms

Case 14-3, Question 9: If B.D. presents with digoxin toxicity, what would be the common signs and symptoms of toxicity?

Digoxin has a narrow therapeutic index, and there is concern for morbidity and death associated with its use. The most important signs of digoxin toxicity are those relating to the heart. A common misperception is that gastrointestinal or other noncardiac signs will precede cardiac toxicity. On the contrary, cardiac symptoms precede noncardiac symptoms of digitalis toxicity in up to 47% of cases. Frequently, nonspecific arrhythmias are the only manifestation of toxicity, with estimates that rhythm disturbances occur in 80% to 90% of all patients with digitalis toxicity.[236] Conversely, rhythm disturbances in patients taking digitalis are not always related to toxicity. In one study of 100 consecutive patients with suspected digitalis-induced arrhythmias, only 24 were confirmed as being toxic as defined by resolution of cardiac irritability after drug withdrawal. In the other 76 patients, the dysrhythmia persisted long after drug removal.[237]

Most arrhythmias can occur as a result of digoxin toxicity. Decreased conduction velocity through the AV node presents as a prolonged PR interval (first-degree AV block) and is seen in many patients with therapeutic concentrations of digoxin. However, higher concentrations of digoxin can impair conduction and result in bradycardia or a second-degree AV block. With severe toxicity, complete (third- degree) AV block can occur. AV block also may predispose patients to accelerated junctional rhythms. Increased automaticity of the atria can cause multifocal atrial tachycardia with block, paroxysmal atrial tachycardia with block, or AF.

Ventricular arrhythmias are among the most common rhythm disturbances caused by digoxin toxicity and include unifocal and

multifocal premature ventricular contractions (PVCs), bigeminy, trigeminy, ventricular tachycardia, and ventricular fibrillation.[236,237] In the DIG trial, 11.9% of patients in the digoxin treatment group were found to have suspected digoxin toxicity compared with 7.9% in the placebo group. Comprehensive reviews are available on the topic of digitalis- induced arrhythmias.[219]

Hyperkalemia can develop as a consequence of massive digoxin ingestion by severely poisoning the Na^+/K^+ ATPase system, causing inhibition of the uptake of potassium by the myocardium, skeletal muscle, and liver cells.[238] The shift of potassium from inside to outside the cell can result in significant hyperkalemia, especially in patients with underlying renal insufficiency. These same patients also accumulate digoxin in the body because of decreased clearance of the drug.

Vague gastrointestinal symptoms characteristic of digoxin toxicity are difficult to evaluate because anorexia and nausea are also part of clinical picture seen in patients with congestion.

CNS symptoms of digoxin are common, possibly associated with potassium depletion in neural tissue. Chronic digoxin intoxication can manifest as extreme fatigue, listlessness, or psychic disturbances in the form of nightmares, agitation, and hallucinations.[239] Visual disturbances have been described as hazy vision and difficulties in both reading and red–green color perception. Other reports included dark or moving spots, photophobia, and yellow–green vision. Disturbances in color vision returned to normal 2 or 3 weeks after discontinuation of digitalis.

Digitalis-induced visual disturbances have been reported at serum concentrations below those considered to be toxic (all <1.5 ng/mL; range, 0.2–1.5 ng/mL).[240] Five of the reactions were described as photopsia (seeing lights not present in the environment), and one person had decreased visual acuity. The symptoms resolved in all but one subject when digoxin was discontinued.

Some prospective studies have shown a good correlation between serum digoxin concentration and toxicity,[239,241,242] whereas other investigators found a poor correlation.[243,244] Once levels exceed 6 ng/mL, the risk of mortality greatly increases.[245] Patients with

hypokalemia can demonstrate digitalis toxicity at low serum digoxin concentrations.[246]

For many patients without life-threatening arrhythmias or major electrolyte imbalances, simple withdrawal of digoxin is the only treatment required. Potassium replacement should be considered in any patient with digoxin-induced ectopic beats who is hypokalemic. Digoxin-specific antibodies that bind digoxin molecules, rendering them unavailable for binding at receptors, are available.[247–252] The use of digoxin Fab products is restricted to potentially life-threatening intoxications (severe arrhythmias or hyperkalemia) that are either refractory to more conservative therapy or associated with extremely high serum digoxin concentrations.

Non–Angiotensin Converting Enzyme Inhibitor Vasodilator Therapy

CASE 14-4

Question 1: T.R. is a 57-year-old African American male (LVEF of 35%) who presents to the HF clinic for follow-up. His BP is 130/79 mm Hg and pulse is 65 bpm. Current medications include lisinopril 20 mg daily, metoprolol succinate 200 mg daily, spironolactone 25 mg daily, hydralazine 25 mg qid, and isosorbide dinitrate 20 mg tid.

Why is the patient on hydralazine and isosorbide? What other forms of nitrates can be used in place of the isosorbide? Is combination therapy rational?

T.R. is treated with an ACEI, a β-blocker, and spironolactone. Despite this therapy, he is still having HF symptoms. He was started on hydralazine and isosorbide dinitrate, which is a possible next step in treating a patient with HFrEF.

Hydralazine's predominate action is as an arteriolar dilator. Decreasing afterload improves LV function. SVR is decreased, and this leads to an increase in CO.[139,253,254] Hydralazine is a direct-acting smooth muscle relaxant with significant arteriolar dilating effects in the kidneys and limbs. It has no effect on the venous system or on hepatic blood flow.

The reflex tachycardia and hypotension that accompany hydralazine in treating HTN are minimal or absent when treating HF. In patients with end-stage cardiomyopathy, significant hypotension can occur if the heart cannot respond appropriately by increasing CO. Because hydralazine is devoid of venous dilating properties, central venous pressure and PCWP are unchanged.[139,254]

The effect of a single dose of hydralazine occurs in about 30 minutes and lasts up to 6 hours. The average maintenance dose is 50 to 100 mg every 6 to 8 hours. T.R. is receiving an initial dose at this time and may warrant a higher dose in the future. Hydralazine used as monotherapy is not associated with long-term improvement in functional status.[254] Combination therapy of hydralazine with either nitrates or ACEIs is highly effective.

Although tachyphylaxis generally is not a significant problem with prolonged courses of hydralazine, some patients require increased diuretic doses to counteract hydralazine-induced fluid retention. This latter response reflects activation of the renin–angiotensin system after vasodilation of the renal vasculature. Other side effects with hydralazine include transient nausea, headache, flushing, tachycardia, and a lupus syndrome associated with prolonged, high doses (see Chapter 9, Essential Hypertension).

ORAL NITRATES

Nitrates have effects complementary to those of hydralazine.[139,253] They primarily dilate venous capacitance vessels. Venous dilation reduces preload, resulting in reductions in PCWP and right atrial pressure. They are especially effective in reducing the symptoms of pulmonary congestion. The lack of significant arterial dilation accounts for the observations that SVR is minimally reduced and CO remains unchanged.

Isosorbide

Because sublingual NTG has a short duration of action, more attention has been focused on isosorbide dinitrate. Sublingual isosorbide dinitrate is well absorbed and does not undergo first-pass

metabolism. Its onset is rapid (5 minutes), but its effects are relatively short (1–3 hours). The usual starting dosage is 5 mg every 4 to 6 hours, but dosages may be titrated to 20 mg or more. Larger doses are associated with longer beneficial effects (~3 hours), but also have a high frequency of headaches and hypotension.

Oral isosorbide has a slower onset (15–30 minutes), but the duration of activity is longer (4–6 hours) than that of sublingual tablets. The smallest effective dose is 10 mg, with titration to dosages as high as 80 mg every 4 to 6 hours. The best dose for both sublingual and oral nitrates is that which provides the desired beneficial effect with the least side effects. Isosorbide mononitrate is frequently used because it is generally given once daily.

HYDRALAZINE–NITRATE COMBINATION

Combined afterload and preload reduction are clearly of benefit in improving symptoms and enhancing long-term survival. Compared with ACEIs, the hydralazine–isosorbide combination provides more improvement in exercise tolerance, but the side effect profile and survival statistics are better with ACEIs.[139] Generally, the use of the two drugs together is not accompanied by reflex tachycardia or hypotension.

Data supporting the use of combination hydralazine and nitrate vasodilator therapy come from two Veterans Administration (VA) Cooperative Studies (V-HeFT I and V-HeFT II).[70,139,253] These two studies confirmed symptomatic relief and improved exercise tolerance with combination therapy, and improved survival. (See Case 14-3, Question 2, for the discussion of the therapy in African American patients.)

In summary, nitrates alone are indicated for those patients with signs and symptoms of pulmonary and venous congestion. Use of an arterial dilator is beneficial in a patient with high SVR and low CO. Most patients, such as T.R., exhibit symptoms of decreased CO and elevated venous pressure, making combination therapy an attractive option. Although the hydralazine–isosorbide combination actually reduces symptoms slightly better than do ACEIs, the data on survival

are better with the ACEIs, probably owing to better adherence. A combination of an ACEI plus hydralazine, a nitrate, or both is common in patients with advanced disease.

Role of Race in the Pharmacotherapy of Heart Failure

CASE 14-4, QUESTION 2: Because T.R. is African American, would he be expected to respond differently to ACEIs or hydralazine– isosorbide dinitrate than a patient who is not African American?

In general, African American patients experience HF at an earlier age and are more likely to have HTN as a cause. The death rate of HF is higher for African American than for non–African American patients.

ANGIOTENSIN CONVERTING ENZYME INHIBITORS AND HYDRALAZINE–ISOSORBIDE

Racial differences in response to drug therapy have been proposed, although this issue is far from resolved.[255–258] A post hoc analysis[256] of the V-HeFT trial data showed no difference in annual mortality between African American and non–African American patients receiving placebo. African American patients in the hydralazine–nitrate group had a significantly lower mortality rate than did those in the placebo group. This implies that African American patients, but not non–African American patients, derive benefit from the treatment with hydralazine–isosorbide. These same investigators then reanalyzed the V-HeFT II trial results for possible racial differences between response to enalapril and the hydralazine–nitrate combination.[139,256] The outcome is difficult to interpret because of the absence of a placebo group. The all-cause annual mortality rate for African American patients was identical in the two drug groups (12.8% with enalapril and 12.9% with hydralazine–isosorbide). In non–African American patients, the corresponding mortality rates

were 11% with enalapril and 14.9% with hydralazine–isosorbide. These data could be interpreted as either superior response to hydralazine–isosorbide in African Americans or inferior response to ACEIs in African Americans. The latter interpretation is consistent with the hypothesis that ACEIs might have a lesser BP-lowering effect in African American patients with HTN. A similar reanalysis of the SOLVD Prevention and Treatment trials,[134] which compared enalapril with placebo in patients with recent MI, concluded that enalapril is associated with a significant reduction in the risk of HF hospitalization among White patients (44% reduction) with LV dysfunction, but not among African American patients. Confounding variables contributing to all of these analyses include disproportionately low numbers of African American subjects in the trials, and possibly more underlying risk factors in African American subjects.

To address the effect of race on response to ACEIs, a meta-analysis of seven major ACEI studies with 14,752 patients, was conducted.[257] The authors concluded that the relative risk for mortality when taking an ACEI compared with placebo was identical (0.89) for both African American and White patients. The authors urged that ACEIs not be withheld from African American patients. Although rare, there is a higher rate of angioedema with ACEIs in Black patients compared to White patients.

The AHeFT previously mentioned was a randomized comparison trial of hydralazine–isosorbide dinitrate versus placebo in African American or self-identified Black patients with NYHA class III or IV HF who were receiving standard HF therapy (diuretics, β-blockers, ACEIs or ARBs, digoxin, and AAs).[71] The primary end point was a composite of all-cause death, first hospitalization for HF, and quality-of-life scores at 6 months. Reduction in the primary end point events was statistically significant in favor of the active drug combination. All-cause mortality declined 43% with hydralazine–isosorbide dinitrate versus placebo ($P = .012$). The study also reported a 39% reduction in first hospitalization for HF with hydralazine–isosorbide dinitrate versus placebo ($P < .001$). The results of AHeFT were also the primary factor leading the FDA to approve the combination

product of hydralazine and isosorbide dinitrate (BiDil) for adjunctive treatment in African American or self-identifying Black patients.

β-BLOCKERS

A possible racial difference in response to β-blocker drugs has also been hypothesized based on effects observed in HTN.[255,257,258] A post hoc analysis of the U.S. Carvedilol Heart Failure trials[189–193] concluded that the benefit of carvedilol was similar in both Black and non-Black patients.[258]

Contradictory evidence comes from BEST.[199] In this trial (discussed in Case 14-1, Question 20), 2708 patients with NYHA class III or IV HF were randomly assigned to either bucindolol or placebo. Bucindolol is a nonselective β-blocker with partial agonist activity that imparts weak vasodilation. A unique characteristic of this study was a preplanned subgroup analysis for racial differences. Although there was a trend toward reductions in CV mortality and hospitalization with bucindolol, the trial was terminated after 2 years. A subgroup analysis showed a mortality benefit in non-Black subjects, but no benefit in Black subjects. A meta-analysis of five major β-blockers in HF studies representing 12,727 patients has been conducted, suggesting that Black patients will derive similar benefit from β-blockers as do White patients when given carvedilol, metoprolol, or bisoprolol.[257]

Critical Care Management of Heart Failure

CASE 14-5

Question 1: L.M., a 62-year-old Black male, was admitted several days ago with severe, progressive, and debilitating symptoms of HF. His family history is significant in that his father and two brothers died of heart attack shortly after age 40. L.M. has a 5-year history of HF that is symptomatic despite treatment with furosemide 40 mg daily, lisinopril 10 mg daily, carvedilol 12.5 mg bid, digoxin 0.125 mg daily, and spironolactone 25 mg daily. His last echocardiogram showed an EF of 25%. He has a past medical history of HTN, CAD, and HF. During the past week, L.M.'s DOE became progressively worse, and he was confined to bed because of fatigue. He wakes once or twice nightly

with PND. Physical examination revealed jugular venous distension, bilateral rales, hepatomegaly, and 3+ peripheral edema. Chest radiograph showed cardiomegaly and pulmonary congestion. His BP was 154/100 mm Hg and pulse was 105 bpm.

Laboratory test results include:

Serum Na^+, 134 mg/dL
K^+, 4.3 mg/dL
BUN, 15 mg/dL
SCr, 1.3 mg/dL
Glucose, 90 mg/dL
BNP, 944 pg/mL

Hemoglobin, hematocrit, troponin, and liver enzymes were within normal limits. L.M. was admitted to the hospital with ADHF.

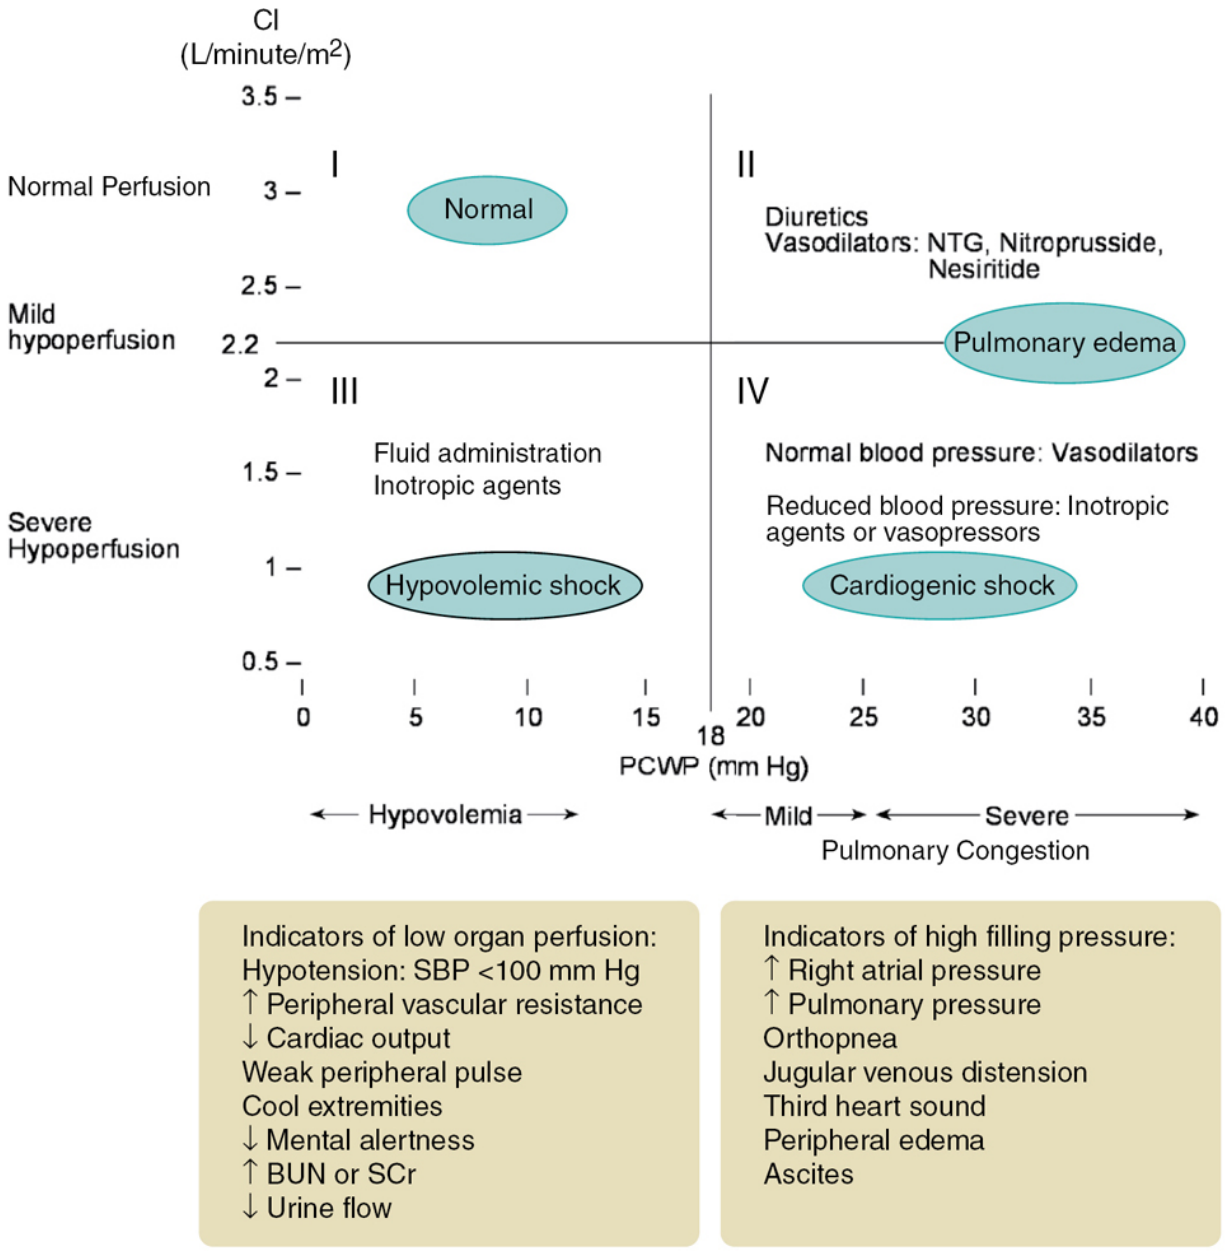
What factors are used to stratify risk for in-hospital mortality and morbidity?

ADHF is associated with high morbidity and mortality. It is the leading reason for hospitalizations among the elderly. Postdischarge mortality among patients with HF is 11% at 30 days and 37% at 1 year.[259] The most common precipitants of HF hospitalization are noncompliance (dietary or medication), acute myocardial ischemia, uncontrolled comorbidities (HTN, diabetes mellitus, chronic kidney disease, arrhythmias), and prescribing of negative inotropic agents, NSAIDs, or other inappropriate agents. Regardless of the precipitating event, the common pathophysiologic state that perpetuates the progression of HF is complex. A cascade of hemodynamic and neurohormonal derangements provoke activation of adrenergic systems and RAAS, leading to volume overload and hypoperfusion—classic symptoms of ADHF. According to the ADHF National Registry, nearly half of the patients who present with ADHF have preserved EF (>50%).[260]

In-hospital mortality remains as high as 20% for patients who present with elevated BUN and creatinine, and low SBP (SCr >2.75 mg/dL, BUN >43 mg/dL, SBP <115 mm Hg).[251] Patients presenting with hyponatremia (serum sodium <135 mEq/L) have the worst outcomes and are more likely to receive inotropic agents. After discharge, patients who continue to be hyponatremic have an 8% risk of rehospitalization per 3 mEq/L decrease in serum sodium. Uric

acid >7 mg/dL in males and >6 mg/dL in females is associated with a high admission rate for HF. Admission and discharge levels of BNP are also helpful in predicting rehospitalizations. According to studies, a 30% to 40% reduction in BNP levels during hospitalization may improve outcomes. Other biomarkers such as cardiac troponin levels, C-reactive protein, and apolipoprotein A-I levels are all linked to HF readmissions.[7] All these factors can be used to stratify risk for in-hospital mortality.

Another approach to risk stratification and therapeutic decision-making is based on hemodynamic profiles. Most patients with acute HF can be classified into one of four hemodynamic profiles using relatively simple assessment techniques (see **Fig. 14-10**).[261–264] Patients are assessed for the presence or absence of elevated venous filling pressures ("wet" vs "dry") and adequacy of vital organ perfusion ("warm" vs "cold"). Elevated filling pressure can be assessed at the bedside by observing jugular venous distension, presence of a third heart sound (S_3), peripheral edema, and ascites. Presence or absence of rales on auscultation is not considered a reliable indicator.[264] Hypotension, weak peripheral pulse, a narrow pulse pressure, cool extremities, decreased mental alertness, and rising BUN and SCr are indicators of decreased organ perfusion. Continuous BP, ECG, urine output, and pulse oximetry measurements are standard noninvasive monitoring for all patients in an intensive care unit. Invasive hemodynamic monitoring is used in critically ill patients when more precise measurements of filling pressures, SVR, and CO or cardiac index are desired. The goals are to achieve a right atrial pressure of <8 mm Hg, pulmonary artery pressure of <25/10 mm Hg, pulmonary artery wedge pressure of 12 to 16 mm Hg, SVR 900 to 1400 dyne second/m^5, and a cardiac index >2.5 L/minute/m^2. (See Chapter 17, Shock, for a more detailed discussion of hemodynamic monitoring.)



Indicators of low organ perfusion:
Hypotension: SBP <100 mm Hg
↑ Peripheral vascular resistance
↓ Cardiac output
Weak peripheral pulse
Cool extremities
↓ Mental alertness
↑ BUN or SCr
↓ Urine flow

Indicators of high filling pressure:
↑ Right atrial pressure
↑ Pulmonary pressure
Orthopnea
Jugular venous distension
Third heart sound
Peripheral edema
Ascites

Figure 14-10 Hemodynamic profile of acute heart failure. BUN, blood area nitrogen; CI, cardiac index; NTG, nitroglycerin; PCWP, pulmonary capillary wedge pressure; SBP, systolic blood pressure; SCr, serum creatinine. (Adapted from Forrester JS, Diamond GA, Swan HJ. Correlative classification of clinical and hemodynamic function after acute myocardial infarction. *Am J Cardiol*. 1977;39(2):137–145. © 1977 Elsevier. With permission.)

CASE 14-5, QUESTION 2: From his clinical presentation, what is L.M.'s hemodynamic profile? What are the therapeutic goals for L.M.?

L.M.'s DOE, rales, peripheral edema, PND, and JVP are consistent with ADHF and volume overload. L.M. does not have signs of hypoperfusion. His hemodynamic profile is "warm and wet" (subset II, **Fig. 14-10**). According to the guidelines, a rapid diagnosis of ADHF is necessary to initiate appropriate treatment. In patients who have established HF, precipitating factors should be identified and addressed. At the time of discharge, medications that decrease morbidity and mortality in HF should be optimized. BNP levels should be considered when the diagnosis is uncertain and can be helpful in differentiating between cardiac and noncardiac causes of dyspnea.

Because volume overload is central to the pathophysiology of most episodes of ADHF, the primary goal is to relieve congestion. However, diuretics should be cautiously used in subset IV to avoid decreases in PCWP <15 mm Hg because this can compromise preload and further reduce CO. Despite diuretics being the main therapy in reducing volume overload, their routine use in ADHF is associated with worsening renal function and mortality. Mortality rates are higher in patients receiving chronic diuretic therapy compared with those not receiving diuretics. These findings are based on retrospective data. Nevertheless, they suggest an association between mortality and diuretic use in patients with ADHF (see Case 14-1, Question 7, for diuretic dosing).

ULTRAFILTRATION

Ultrafiltration is an alternative approach for treating hypervolemia. It involves the use of a small device to rapidly remove fluid (up to 500 mL/hour). Typically, ultrafiltration for HF is reserved for patients with renal failure or those unresponsive to diuretics. Studies[265,266] in patients with ADHF have shown that peripheral venovenous ultrafiltration results in greater weight loss and fluid removal, and reduced hospital length of stay and hospital readmissions compared

with medical therapy. Significant reductions in neurohormonal activation and no significant changes in SCr or electrolytes were reported with ultrafiltration.[267] The Ultrafiltration versus Intravenous Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure (UNLOAD trial)[268] randomly assigned 200 patients to either ultrafiltration or aggressive IV diuretic therapy. The study showed that ultrafiltration significantly improved weight loss at 48 hours (5.0 vs 3.1 kg; $P < .001$), decreased the need for vasoactive drugs (3% vs 13%; $P = .02$), and reduced 90-day hospital readmission (18% vs 32%; $P = .02$) compared with diuretics alone. Ultrafiltration has a class IIb recommendation for patients with refractory HF not responsive to medical therapy. Patients with fluid overload and some degree of renal insufficiency and those refractory to diuretic therapy are candidates for ultrafiltration.[2]

Intravenous Vasodilators

Case 14-5, Question 3: L.M. received a 40-mg IV furosemide dose with no improvement in symptoms. Then he received an 80-mg IV dose with only marginal improvement. The decision is made to start nitroprusside. What is the role of IV vasodilator therapy in someone with ADHF?

The guidelines recommend the addition of vasodilators(IV NTG or nitroprusside) in conjunction with diuretics to reduce congestion in patients with fluid overload in asymptomatic hypotension. In the presence of asymptomatic hypotension, IV NTG, or nitroprusside, in combination with diuretics. In the presence of low SVR, arterial vasodilators (eg, nitroprusside, high-dose NTG) can further compromise perfusion and should be avoided, especially in patients who have preexisting hypotension.

NITROPRUSSIDE

Nitroprusside dilates both arterial and venous vessels, decreasing afterload and preload. Nitroprusside is valuable in patients who are severely congested and have HTN or severe mitral valve

regurgitation complicating LV dysfunction. Its major disadvantages include risk of hypotension, reflex tachycardia, “coronary steal” in patients with CAD, and accumulation of toxic metabolites. Thiocyanate and cyanide toxicity are most likely seen in renal insufficiency and in patients who receive >4 µg/kg/minute of nitroprusside for >48 hours. When stopping nitroprusside therapy, a slow taper is recommended because a rebound increase in HF has been observed 10 to 30 minutes after drug withdrawal (see Chapter 16, Hypertensive Crises).

Nitroprusside must be given by continuous IV infusion, with arterial line placement and intensive care unit admission in most institutions. It is unstable if exposed to heat and light after reconstitution.

INTRAVENOUS NITROGLYCERIN

NTG primarily dilates the venous capacitance vessels with a slight effect on the arterial bed. Patients with acute MI and pulmonary edema are often considered ideal candidates for IV NTG. The resulting reduction in preload reduces PCWP. Because nitrates have minimal effect on afterload, CO will likely remain unchanged or increase slightly. In some patients, NTG could decrease CO if preload is reduced to <15 mm Hg. NTG is generally initiated at 10 µg/minute and increased by increments of 10 to 20 µg, until the patient’s symptoms are improved or PCWP is <16 mm Hg. The most common side effect is headache, which can be treated with analgesics and often resolves after continuous therapy. Tachyphylaxis to NTG occurs within 24 hours of initiation of therapy. Approximately 20% of patients with HF exhibit resistance to high doses of NTG.[2] Nitroprusside is a good choice for patients such as L.M. because he has elevated BP and no history of CAD.

Inotropic Agents

DOPAMINE AND DOBUTAMINE

CASE 14-6

QUESTION 1: B.J. is a 60-year-old male who presents to the ED with worsening DOE. He reports increased SOB during the past week. His medical history includes HTN, CAD, hyperlipidemia, and HF (EF 25%). His medications include metoprolol succinate 100 mg daily, enalapril 5 mg twice daily, furosemide 40 mg bid, aspirin 81 mg daily, and lovastatin 20 mg at bedtime. His vital signs on admission include BP 100/75 mm Hg, HR 92 bpm, respiratory rate 18 breaths/minute, and O_2 saturation 94% on room air. Laboratory values were BUN 20 mg/dL and SCr 1.4 mg/dL. Physical examination reveals pulmonary and peripheral edema and JVP 10 cm. He is given 80 mg IV furosemide with minimal response. His dose was increased to 120 mg IV furosemide, and he still does not respond adequately. Within the past 24 hours, his SCr has increased to 1.8 mg/dL, and his BP is 92/70 mm Hg. The decision is made to admit him to the coronary care unit where a pulmonary artery catheter (Swan–Ganz catheter) is placed, and the hemodynamic variables are as follows: PCWP 21 mm Hg; CO 3.64 L/minute (cardiac index 1.8 L/minute/m^2); SVR 1489 dyne second/cm^5.

Is B.J. a candidate for inotropic therapy?

The hemodynamic profile of B.J. is category IV (cold and wet) because of hypoperfusion and congestion. According to the ACC/AHA guidelines,[1] IV inotropic agents (dobutamine, dopamine, milrinone) are indicated in symptomatic patients with reduced LVEF, low CO, or end-organ dysfunction (ie, worsening renal function) and in patients who are intolerant to vasodilators. They are recommended for patients with cardiogenic shock or refractory symptoms and may be used in patients requiring perioperative support after surgery or for those awaiting transplantation. Dobutamine is usually preferred in patients with low-output HF. Dobutamine improves CO, decreases PCWP, and decreases total SVR with little effect on HR or systemic arterial pressure when compared with dopamine.[269] (See Chapter 17, Shock, for further information on dopamine and dobutamine.)

PHOSPHODIESTERASE INHIBITORS: MILRINONE

Although β-agonists, such as dobutamine, have been traditionally used in patients with ADHF, the PDE inhibitor milrinone is an alternative to the catecholamines and vasodilators for the short-term parenteral treatment of severe congestive failure. This agent

selectively inhibits PDE III, the cyclic adenosine monophosphate (cAMP)-specific cardiac PDE. Enzyme inhibition results in increased cAMP levels in myocardial cells and enhances contractility. The activity is not blocked by β-blockers. PDE inhibitors are also vasodilators. It has been suggested that at low doses they act more as unloading agents rather than as inotropic agents; others refute this viewpoint. Their overall hemodynamic effect probably results from a combination of positive inotropic action plus preload and afterload reduction.

Milrinone is structurally and pharmacologically similar to inamrinone, which is no longer used.[270–272] Besides inhibiting PDE, it also may increase calcium availability to myocardial muscle. It has both inotropic and vasodilating properties. HR increase and myocardial consumption may be less with milrinone than with dobutamine.[273,274] The half-life of milrinone is 1.5 to 2.5 hours, with renal clearance accounting for ~80% to 90% of total body elimination and is prolonged in patients with renal dysfunction. Although a loading dose of 50 μg/kg is in the product labeling, it is rarely given because of resulting hypotension. Maintenance infusions are typically between 0.2 and 0.75 μg/kg/minute. The infusion is adjusted according to hemodynamic and clinical responses and should be decreased in patients with renal insufficiency. The primary concern with milrinone is ventricular arrhythmias, reported in up to 12% of patients. Supraventricular arrhythmias, hypotension, headache, and chest pain also have been reported. Thrombocytopenia is rare.

The Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) trial assessed the in-hospital management of 951 patients with acute HF exacerbation (mean LVEF 23%) but not in cardiogenic shock.[273,274] In addition to standard diuretic and ACEI therapy, subjects were randomly assigned to receive either milrinone or placebo. The initial milrinone infusion rate was 0.5 μg/kg/minute with no loading dose. The primary end point was total numbers of days hospitalized for CV causes from the time of the start of study drug infusion to day 60. No difference was found between milrinone and placebo with mortality

at 60 days (10.3% with milrinone and 8.9% with placebo).[273] Follow-up analysis categorized subjects as ischemic versus nonischemic.[274] Within the cohort of patients with ischemia, patients treated with milrinone tended to have worse outcomes than did those treated with placebo. In contrast, patients who were nonischemic had a trend toward better outcomes with milrinone than with placebo. From these data, it can be concluded that the benefits of milrinone in patients with acute exacerbations of HF are minimal and more likely to be seen in patients with a nonischemic etiology of HF. Worse outcomes may be seen in patients with ischemic HF. However, short-term infusions of milrinone were not associated with excess mortality.

Few trials have compared dobutamine to milrinone in ADHF. One small retrospective analysis evaluated 329 patients admitted for ADHF (EF of <20%) who either received IV dobutamine or milrinone.[275] Hemodynamic response, need for additional therapies, adverse effects, length of stay, and drug cost were evaluated. Patients were similar in clinical presentation, but the milrinone group had higher mean pulmonary arterial pressure. A greater percentage of patients received dobutamine (81.7%) versus milrinone (18.3%). Only 19% of patients were taking β-blockers before admission. Clinical outcomes were similar and there was no significant difference in the in-hospital mortality rate, adverse effects, ventilator use, or length of stay. More patients in the dobutamine group required nitroprusside to achieve optimal hemodynamic response. The study concluded that both drugs have comparable efficacy.

Other factors to consider when deciding which inotropic agent should be used in ADHF are renal function, BP, and concomitant β-blocker use. Milrinone has a longer half-life than dobutamine and accumulates in cases of renal dysfunction. Milrinone is also a vasodilator, which can limit its use in patients with hypotension. The concomitant use of β-blockers may antagonize the action of dobutamine.

B.J. has responded poorly to IV furosemide, his renal function has deteriorated, and his SBP is low. Patients with advanced HF and systemic hypoperfusion often will not tolerate vasodilator therapy. Inotropic agents may be necessary to maintain circulatory function in

these patients. According to guidelines, IV inotropic drugs may be considered for patients who have symptomatic hypotension despite adequate filling pressure, who are unresponsive to diuretics and intolerant to vasodilators, or who have worsening renal function. PDE inhibitors are sometimes preferred over dobutamine for patients who are receiving concomitant β-blockers. For the abovementioned reasons, B.J. is a candidate for milrinone therapy. Patients should be on telemetry because milrinone has the potential to cause arrhythmias. Vital signs, SCr, symptom relief, and urine output should be monitored. Once the patient's hemodynamic profile improves, milrinone should be discontinued, and oral furosemide therapy can be resumed. At discharge, the outpatient HF medications should be optimized.

Outpatient Inotropic Infusions

Case 14-6, Question 2: Are there any indications for using repeated intermittent infusions of inotropic agents as part of a home care regimen?

The long-term safety and efficacy of inotropic therapy is regarded with skepticism. There are few studies assessing intermittent (eg, weekly) infusions of dobutamine or milrinone. Nearly all the data on this therapeutic approach are from open-label and uncontrolled trials that compare two inotropic agents without a placebo.[276–280] It is thought that long-term therapy may be cardiotoxic. The only placebo-controlled trial of intermittent infusion of dobutamine was terminated because of excess mortality with dobutamine.[277] Death occurred in 32% of patients treated with dobutamine versus 14% with placebo. Whether this was caused by progression of underlying heart disease, continued drug therapy, or was a cardiotoxic effect remains unknown. No corresponding data exist for milrinone, although a placebo-controlled trial with milrinone failed to support the routine use of IV milrinone as an adjunct to standard therapy in the treatment of patients hospitalized for an acute exacerbation of chronic HF.[273,274] For this reason, the ACA/AHA guidelines indicate

that intermittent infusions of dobutamine and milrinone in the long-term treatment of HF, even in advanced stages, should be avoided.[4] Chronic continuous infusions of dobutamine and milrinone are sometimes administered in patients with refractory HF as palliative therapy or in those awaiting transplant. The lowest dose possible should be administered. The HFSA identifies the limited treatment options in advanced HF and proposes patient-centered outcomes (survival vs quality of life, palliative, and hospice care) to be incorporated into care plans.[281]

Ventricular Arrhythmias Complicating Heart Failure

AMIODARONE

Case 14-6, Question 3: B.J. was stabilized during the next several days and discharged home with furosemide 40 mg daily, enalapril 5 mg twice daily, metoprolol succinate 100 mg daily, aspirin 81 mg daily, and NTG 0.4 mg sublingual to be used as needed for chest pain. His EF is 23%. Laboratory values were normal. ECG monitoring during B.J.'s hospital stay showed normal sinus rhythm, with 15 to 20 asymptomatic PVCs/hour. At that time, it was decided not to treat his arrhythmia other than with metoprolol because he was asymptomatic. For the next several months, he continued to have frequent PVCs during follow-up examinations.

It has now been 5 months and he is still having up to 12 to 15 PVCs/hour. His exercise capacity is limited by SOB after walking about a block despite having enalapril increased to 20 mg/day, metoprolol succinate to 200 mg/day, and adding digoxin 0.25 mg/day. The furosemide is at 40 mg/day because he has edema. A repeat echocardiogram shows an EF of 20%. Is an antiarrhythmic agent indicated for B.J. at this time? What is the agent of choice, and what dose should be given?

PVCs and other arrhythmias are a common complication of LV dysfunction and may be present regardless of whether the patient has had an MI. Approximately 50% to 70% of patients with HF have episodes of nonsustained ventricular tachycardia on ambulatory monitoring. This myocardial irritability may be a result of autonomic hyperactivity or ventricular remodeling. It is not clear whether these

rhythm disturbances contribute to sudden death or simply reflect the underlying disease process. Recent studies suggest that bradyarrhythmia or electromechanical dissociation may be associated with sudden death in patients with HF having nonischemic cardiomyopathy.[282,283] More importantly, suppression of ventricular ectopy in patients with HF has not been shown to lead to a reduction in sudden death in clinical trials. Neither prophylactic antiarrhythmic therapy nor treatment of asymptomatic PVC after an MI has been proved to improve outcome or survival. Because of concerns about the proarrhythmic effects of most class IA and class IC drugs, treatment with these agents is contraindicated.

Amiodarone has value in patients with HF with arrhythmias because it has antiarrhythmic and coronary vasodilating effects as well as α- and β-blocking properties. It may offer a dual benefit to reduce myocardial irritability and improve the hemodynamics of HF.

In the Grupo de Estudio de la Sobrevida en la Insuficiecia Cardiaca en Argentina (GESICA) study,[284] 516 patients with class II to IV HF symptoms (average EF 20%), and frequent PVCs were randomly assigned to receive either standard treatment (diuretics, vasodilators, digoxin) or a fixed dose of amiodarone plus standard treatment. The dose of amiodarone was 600 mg daily for 2 weeks, then 300 mg/day for at least 1 year. Fewer patients on amiodarone (33.5%) died compared with those receiving standard treatment (41.4%), a statistically significant difference. Similarly, the number of HF-related hospitalizations was reduced with amiodarone.

Somewhat different outcomes were noted in the VA Cooperative Survival Trial of Antiarrhythmic Therapy in Congestive Heart Failure (CHF-STAT) study.[285,286] Entry criteria to this trial were similar to those in the GESICA study, with a primary indicator being >10 asymptomatic PVCs per hour on 24-hour monitoring, but without sustained ventricular tachycardia. A higher dose of amiodarone was used, 800 mg for 2 weeks, then 400 mg/day for 1 year. The dose was reduced to 300 mg/day after the first year, with the average follow-up being 45 months. No difference was found between groups for either all-cause mortality or SCD. EF improved more in the patients treated with amiodarone, rising from a baseline average of

24.9% to 33.7%. The corresponding change in the standard treatment group was from a baseline of 25.8% to 29.2% at follow-up. Despite the increase in EF, symptom scores did not differ between the two groups.

Amiodarone does not have a negative effect on mortality as seen with some of the other antiarrhythmic agents. Other factors to consider are the potential for significant side effects with amiodarone (see Chapter 15, Cardiac Arrhythmias) and the drug interaction with digoxin leading to the potential for digoxin toxicity.

The ACC/AHA guidelines do not recommend routine ambulatory ECG monitoring to detect asymptomatic ventricular arrhythmias and recommend against treatment if such arrhythmias are inadvertently detected.[2,11,45] If symptomatic ventricular arrhythmias should arise or there is determined to be a high risk of sudden death, one of the following should be considered: a β-blocking drug, amiodarone, or an ICD. Nearly all patients with HF should have a β-blocker as part of their regimen because these drugs reduce all-cause mortality, not just sudden death. B.J. continued to have ectopy despite continued use of a β-blocker. Nonetheless, it is decided not to use amiodarone because he is asymptomatic.

Case 14-6, Question 4: The medical resident on your team wants to switch B.J. to ARNI. What is the appropriate time to initiate or switch to sacubitril/valsartan in acute heart failure?

ADHF is associated with high rates of mortality, occurring early after discharge and 30-day rehospitalizations. β-Blockers, ACEIs, or ARBs at the time of hospital discharge for ADHF are not only associated with significant reductions in mortality and hospital readmission but also shown to improve adherence of GDMT if initiated postdischarge. The initiation of sacubitril/valsartan in the ambulatory setting has clearly shown mortality benefits; however, evidence continues to evolve in the ADHF setting. Two clinical trials[287,288] were designed to determine whether it is feasible to safely start ARNI in patients decompensated after hemodynamic

stabilization. In addition, these studies also report initiation and uptitration of sacubitril/valsartan in ACEI/ARB-naive patients, which has also been not well studied.

The safety and efficacy of initiating sacubitril/valsartan in hospitalized patients with acute decompensated HFrEF was evaluated in the com*P*ar*I*son *O*f sacubitril-valsarta*N* versus *E*nalapril on *E*ffect on NT-p*R*oBNP in patients stabilized from an acute *H*eart *F*ailure episode (PIONEER-HF) trial.[287] This was a prospective, multicenter, double-blind, randomized, controlled trial that included patients with LVEF ≤40% within the past 6 months, NT-proBNP ≥1600 pg/mL or BNP ≥400 pg/mL (screening), stabilized in hospital without symptomatic hypotension (SBP >100 mm Hg) and no increased need for IV diuretics, vasodilators in the prior 6 hours, or inotropes in the prior 24 hours. Patients were either randomized to enalapril (starting at 2.5 or 5 mg, eventually ramped up to 10 mg by mouth [PO] twice daily) or sacubitril/valsartan (starting at 24/26 twice daily and uptitrated to 97/103 twice daily) with dosing determined by SBP.

Unlike the PARADIGM-HF trial, PIONEER-HF[287] included patient populations that were underrepresented: new HF (34.4%), ACEI and ARB naive (52.1%), and a higher proportion of Black (35.9%). The primary end point of time-averaged reduction in the NT-proBNP was significantly greater in the sacubitril/valsartan group than that in the enalapril group (ratio of change 0.71; 95% CI 0.63–0.81; $P < .001$) with the effect evident at 1 week. Sacubitril/valsartan advantages over enalapril were consistent throughout all predefined subgroups, including those with or without prior HF and with a history or no history of prior ACEIs or ARBs. Rates of worsening renal function, hyperkalemia, and symptomatic hypotension and angioedema did not differ between the two groups.

In the subsequent secondary analysis[289] of the PIONEER-HF trial, which was an additional 4-week follow-up in an open-label extension (weeks 8–12), during which all patients were switched to receiving S/V from enalapril at week 8. There was a further 37% reduction in NT-proBNP levels in those who were switched to S/V. Although not powered, an early in-hospital initiation of ARNI resulted in a 31% risk

reduction (RR) in incidence of HF rehospitalization or CV death compared with those who were started on enalapril in the hospital and switched to ARNI 8 weeks post hospitalization (HR, 0.69; 95% CI 0.4–0.97).

Findings from the PIONEER-HF study complement those from the comparison of pre- and postdischarge Initiation of sacubitril/valsartan in hemodynamically stabilized heart failure patients in hospital or early after discharge (TRANSITION). The TRANSITION-HF assessed the tolerability and optimal timing for the initiation of sacubitril/valsartan after stabilization of patients with ADHF either ≥12 hours predischarge or at any point postdischarge (up to 14 days). This trial demonstrated that in ADHF, sacubitril/valsartan was tolerated and maintained at the twice-daily dosage of either 100 or 200 mg in 62.5% and 68.0% of patients pre- and postdischarge, respectively (P = .07). There were no differences in the safety profiles throughout the 10-week postdischarge period. Hypotension was observed in about 12% of the predischarge initiation group and 9% of those starting the drug after discharge, but hypotension did not lead to permanent discontinuation of the therapy. Interestingly, in the trial, 24% of participants had no prior exposure to an ACEI or ARB.

The data from the PIONEER-HF and TRANSITION studies demonstrate that sacubitril/valsartan treatment can be initiated safely before discharge or soon after discharge. Secondary analysis of PIONEER-HF also demonstrates that in-hospital initiation of sacubitril/valsartan leads to an early improvement in postdischarge outcomes. The clinical benefit of sacubitril/valsartan now extends to de novo patients with HF and patients who are ACEI/ARB naive. The 2021 American College of Cardiology Expert Consensus Decision Pathway for Optimization of Heart Failure[45] Treatment makes an allowance for considering such de novo sacubitril/valsartan in "… well-informed patients who, within a framework of shared-decision making, accept the uncertainty about effectiveness and safety as well as potentially greater out-of-pocket costs."

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

CASE 14-6, QUESTION 5: Is B.J. a candidate for an ICD implantation?

Although amiodarone is the preferred antiarrhythmic agent in patients with HF with reduced EF to prevent recurrent AF and symptomatic ventricular arrhythmias, it has not improved survival. Ventricular arrhythmias are associated with a high frequency of SCD in patients with HF. Numerous trials have established the role of ICDs in primary and secondary prevention of SCD. The earliest of the primary prevention trials was the Multicenter Automatic Defibrillator Implantation Trial (MADIT).[290] This study was terminated early because of the survival benefit seen in the ICD group compared with conventional therapy. There was no evidence that amiodarone, β-blockers, or any other antiarrhythmic therapy had a significant influence on the results. Unlike MADIT, the MADIT II[291] study enrolled patients with no documented arrhythmias but with previous MI and LVEF <30%. Patients received either an ICD or a conventional medical therapy. The primary end point was death from any cause. There was a 31% relative reduction in the risk of death and an absolute reduction of 6% in the ICD group. This was the first trial to show mortality benefits of ICDs in patients with no documented history of abnormal heart rhythms.

The Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) evaluated the efficacy of amiodarone in patients with LV dysfunction (EF ≤35%).[292] The patients (NYHA classes II–III) were receiving conventional therapy and randomly assigned to placebo, amiodarone, or an ICD. Amiodarone was no better than placebo, whereas ICD decreased mortality by 23% (P = .007). A subgroup analysis showed that patients with class II HF had a greater drop in mortality with ICD use than did class III patients, whereas amiodarone decreased survival in class III. The role of amiodarone in patients with NYHA class III needs to be further evaluated before it is routinely used in patients with LV dysfunction.

The ACC/AHA guidelines[1] recommend the use of ICDs in patients after MI with reduced LVEF and who have a history of ventricular arrhythmias. ICDs are also recommended for primary prevention in patients with nonischemic cardiomyopathy and ischemic heart disease who have an LVEF of ≤30%, those with NYHA functional class II or III symptoms while on optimal standard oral therapy, and patients who have reasonable expected survival with a good functional status of ≥1 years. Patients with ischemic heart disease should receive an ICD at least 40 days after MI. B.J. is currently on an optimal HF drug regimen, and his EF is 20%. According to guidelines, B.J. would benefit from ICD implantation.

CARDIAC RESYNCHRONIZATION THERAPY

CASE 14-7

QUESTION 1: C.M., a 49-year-old female with a history of cardiomyopathy (EF 25%), presents to the HF clinic with NYHA class III symptoms. She reports increased SOB, chest pain, and fatigue. She has been optimized on drug therapy for 3 months. Her medications include metoprolol succinate 200 mg daily, furosemide 40 mg bid, lisinopril 20 mg daily, and spironolactone 25 mg daily. An ECG showed sinus rhythm at a rate of 72 bpm and a QRS duration of 144 ms.

Is she a candidate for CRT?

Approximately one-third of the patients with advanced systolic HF exhibit intraventricular or interventricular conduction delays that cause the ventricles to beat asynchronously.[293] Ventricular desynchrony is seen on ECG as a wide QRS complex with an LBBB and can lead to deleterious effects on cardiac function. Patients may present with reduced EF, decreased CO, and presence of NYHA class III or IV HF symptoms. These are all associated with increased mortality.

CRT is the use of cardiac pacing to coordinate the contraction of the left and right ventricles.[76] Initial randomized trials of CRT show reduced HF symptoms and improved exercise tolerance and quality of life. The Comparison of Medical Therapy, Pacing, and Defibrillator

in Heart Failure (COMPANION) trial[77] enrolled 1520 patients with NYHA class II or IV (QRS interval of at least 120 ms, and LVEF ≤35%) who were treated with optimal drug therapy (ACEIs, diuretics, β-blockers, and spironolactone). Patients were randomly assigned to receive optimal drug therapy alone, optimal drug therapy and CRT with a pacemaker, or optimal drug therapy and CRT-D. The primary end point was a composite of all-cause mortality and hospitalization. Both the CRT and CRT-D groups were associated with a decreased risk of primary end point compared with optimal drug therapy alone. All-cause mortality at 1 year was decreased by 24% in the CRT group (which did not reach statistical significance) and 43% in the CRT-D group.

The results of the *CA*rdiac *RE*synchronization in *H*eart *F*ailure (CARE-HF)[76] study extended the findings of the COMPANION trial. CARE-HF demonstrated a significant all-cause mortality reduction for CRT pacing without defibrillator backup (CRT) in patients with HF who received similar medical treatment. The inclusion criteria were NYHA class III or IV, EF of ≤35%, and QRS duration of ≥120 ms. The primary end point of all-cause deaths and hospitalizations for a CV reason occurred in fewer patients with CRT compared with the optimal drug therapy (39% vs 55%; $P < .001$). Death or hospitalization for worsening HF was also significantly reduced with CRT.

The combined results of CARE-HF and COMPANION confirm the importance of CRT and CRT-D in improving ventricular function, HF symptoms, and exercise tolerance, while also reducing frequency of HF hospitalizations and death.[294] The role of CRT in patients with mild HF symptoms, narrow QRS, chronic AF, and right bundle branch block needs to be explored.

According to the ACC/AHA guidelines,[2] patients with NYHA class III and ambulatory patients with class IV HF should receive CRT (unless contraindicated) if they meet the following criteria: LVEF of ≤35%, presence of a wide QRS (>120 ms) and receiving optimal HF standard medical therapy. Despite optimal doses of HF medications, C.M. continues to have HF symptoms. CRT could provide incremental benefits beyond what is provided with drug therapy.

Case 14-7, Question 2: If C.M. presented with NYHA class I or II symptoms, would she be a candidate for CRT therapy? What is the evidence to support CRT in NYHA classes I and II patients?

As mentioned in Case 14-6, Question 1, the CARE-HF and COMPANION trials provide strong evidence that CRT induces reverse modeling in patients with symptomatic NYHA class III and ambulatory class IV HF. The next logical step was to evaluate the benefits of CRT therapy in patients with HF with milder symptoms. The Multicenter InSynch ICD Randomized Clinical Evaluation (MIRACLE-ICDII)[295] trial randomized patients with classes II through IV HF but with separate specified end points for class II patients. In this trial, 186 patients with NYHA class II HF, an LVEF of <35%, and a QRS of >130 ms received a CRT-ICD device. Subjects were randomly assigned to active CRT group (ICD activated and CRT on) or control group (ICD activated and CRT off). The primary end point was progression of HF, defined as all-cause mortality, hospitalizations for HF, and ventricular tachycardia or ventricular fibrillation requiring device intervention. A 15% reduction in HF progression was observed with active CRT but did not reach statistical significance. At 6 months, patients with active CRT had improved exercise tolerance, but this was not significantly different from that seen in the control group. However, there was a significant decrease in ventricular end-systolic volume and increased LVEF after 6 months of therapy. Even though the study results did not translate into improved exercise tolerance, it helped set the stage for future trials in patients with less symptomatic HF.

The **RE**synchronization re**VE**rses **R**emodeling in **S**ystolic left v**E**ntricular dysfunction (REVERSE) trial[74] enrolled 610 participants with NYHA class I or II HF, LVEF <40%, and with a QRS duration of >120 ms who received a CRT device (with or without ICD) in combination with optimal drug therapy. The patients in the active CRT group had significant improvement in LV end-systolic volume index, LV end-diastolic volume index, and LVEF compared to those in the control group. The primary clinical end point (the percentage of

patients with worsened clinical composite score) did not reach statistical significance at 12 months in patients enrolled in the United States; but in the European cohort,[296] a significant difference was seen at 24 months, primarily driven by the time to first hospitalization. The aggregate data from these two clinical trials provided overwhelming evidence that linked CRT with substantial reverse remodeling in patients with mild HF.

The MADIT-CRT[75] was the largest randomized trial designed to determine whether CRT-D therapy would reduce the primary end point (all-cause mortality or HF events) when compared with patients receiving ICD-only therapy. The study population involved patients with cardiac issues in NYHA functional class I or II with LVEF of ≤30% and QRS duration of >130 ms. There was a 34% ($P < .001$) reduction in the primary end point, and a 44% ($P < .001$) reduction in HF events when compared with ICD therapy. Patients with CRT-D therapy showed an 11% improvement in LVEF after 1 year, compared with a 3% improvement for patients on ICD alone. Both MADIT-CRT and REVERSE excluded patients with AF. Both studies failed to show a benefit for CRT in patients with QRS duration <150 ms.

The *R*esynchronization/defibrillation for *A*mbulatory heart *F*ailure *T*rial (RAFT)[297] confirmed that CRT benefited patients with a QRS duration of ≥150 ms and in those with LBBB. The RAFT investigators randomly assigned 1798 patients with NYHA class II or III HF, LVEF of ≤30%, and a QRS duration of at least 120 ms (or a paced QRS of at least 200 ms) to either ICD therapy alone or a CRT-D. The primary outcome was a combination of total mortality and HF hospitalization, which was significantly higher in the ICD group compared with the ICD-CRT group (40% vs 33%, respectively). These findings demonstrate that earlier intervention with CRT-D, in addition to guideline-recommended medical and ICD therapy, benefits this patient population.

HEART FAILURE WITH PRESERVED EJECTION FRACTION

CASE 14-8

QUESTION 1: D.F., a 72-year-old White female, has a 5-year history of HF symptoms, including decreased exercise capacity, SOB, and distended neck veins. She has minimal peripheral edema. History is suggestive of rheumatic fever as a child, but she does not recall having any cardiac symptoms when she was younger, other than being told she had a murmur. Her symptoms are controlled with diuretics. She has HTN but no other medical problems, and all laboratory test findings are normal. Her BP is 155/85 mm Hg, and HR is 90 bpm. Cardiac examination reveals a prominent S_4 heart sound. Echocardiography reveals an EF of 50%. Prior treatment included furosemide, most recently at 40 mg bid. The physician is considering adding a β-blocker or CCB to control the BP and HR.

Why might this consideration be appropriate?

This case exemplifies a patient with HFpEF, previously referred to as diastolic HF. Risk factors for HFpEF include advanced age, female sex, HTN, and CAD. This diagnosis can be made on the basis of LVH, clinical evidence of HF, a normal EF, and echocardiography findings. The ideal treatment for HFpEF has not been extensively validated. A review of trials evaluating specific drug therapy in HFpEF is listed in **Table 14-14**. No drug selectively enhances myocardial relaxation without having associated effects on LV contractility or on the peripheral vasculature.[10,298]

Table 14-14
Clinical Trials of Pharmacotherapy in Heart Failure With Preserved Ejection Fraction

Study	Patient Population	Therapy Intervention	Outcome	Treatment Duration	Results
Aronow and Kronzon[331]	NYHA III; Prior MI, EF >50%; (*N* = 21)	Enalapril vs placebo	NYHA class, treadmill exercise time (seconds)	3 months	Enalapril: NYHA class from 3 ± 0 to 2.4 ± 0.5 (*P* = .005), exercise time from 224 ± 27 to 270 ± 44 (*P* < .001) vs no difference in placebo
Lang et al[332]	HF symptoms >3 months; EF >50%; (*N* = 12)	Lisinopril vs placebo crossover	Dyspnea and fatigue	5 weeks for each treatment arm	No significant differences
Cleland et al[300] PEP-CHF	Diastolic dysfunction; CV admission within 6 months; EF >40%; (*N* = 850)	Perindopril vs placebo	Primary: composite of all-cause mortality or hospitalization for HF	Mean 26.2 months	Primary: 23.6% in perindopril group vs 25.1% in placebo (HR 0.92 [0.70–1.21], *P* = .545)
Zi et al[333]	NYHA class II or III; EF ≥40%; (*N* = 74)	Quinapril vs placebo	6-minute walk test, QoL, NYHA class	6 months	No significant differences
Yusuf et al[155] CHARM-Preserved	NYHA II–IV; hospitalization for CV causes; EF >40%; (*N* = 3023)	Candesartan vs placebo	Primary: CV death or hospital admission for HF	Median 36.6 months	Primary: 22% in the candesartan group vs 24% in the placebo group (adjusted HR 0.86 [0.74–1.00], *P* = .051)
Massie et al[302] I-PRESERVE	NYHA II–IV; hospitalized for HF in last 6 months; EF ≥45%; (*N* = 4122)	Irbesartan vs placebo	Primary: all-cause death or hospitalization for CV causes	Mean 49.5 months	Primary: 36% in the irbesartan group vs 37% in the placebo group (HR 0.95 [95% CI 0.86–1.05], *P* = .35)
Yip et al[334]	NYHA II–IV; history of HF in last 2 months; EF >45%; (*N* = 151)	Ramipril vs irbesartan	QoL, 6-minute walk test, HF hospital admission	12 months	No significant differences
Warner et al[335]	Diastolic dysfunction; DOE; EF >50%; SBP >150, <200 mm Hg (*N* = 20)	Losartan vs placebo crossover	Exercise time, QoL	2 weeks for each treatment arm	Increase in exercise time (11.3 minutes at baseline, improved to 12.3 ± 2.6 minutes with losartan vs 11.0 minutes with placebo, *P* < .05) and improvement in QoL (25 at baseline, improved to 18 with losartan vs 22 with placebo); *P* < .05 for both end points
Parthasarathy et al[336]	Diastolic dysfunction; DOE; EF >40%; (*N* = 152)	Valsartan vs placebo	Primary: exercise time	14 weeks	No significant differences
Takeda et al[337]	NYHA II–III and stage C heart failure; EF ≥45%	Carvedilol vs placebo	Plasma BNP, NYHA class, exercise capacity	12 months	NYHA class improved by 0.77 (carvedilol) vs 0.25 (placebo) (*P* < .02), exercise capacity in METs improved 0.69 (carvedilol) vs worsened by 0.07 (placebo) (*P* = .01).
Flather et al[303] SENIORS	HF hospital admission in last year; EF ≤35%; subgroup EF ≥35%	Nebivolol vs placebo	Primary: composite of all-cause mortality or hospitalization for a cardiovascular cause	Mean 21 months	EF >35%, primary event rate 17.6% in nebivolol and 21.9% in placebo (HR 0.86 [95% CI 0.74–0.99], *P* = .039)
Aronow et al[338]	NYHA II–III; prior Q-wave MI; EF >40%; (*N* = 158)	Propranolol vs placebo	All-cause mortality, all-cause mortality plus nonfatal MI	32 months	All-cause mortality (56% propranolol group vs 76% placebo group, *P* = .007) and all-cause mortality plus nonfatal MI (59% propranolol vs 82% placebo, *P* = .002)
Setaro et al[339]	Abnormal diastolic filling; EF >45%; (*N* = 20)	Verapamil vs placebo	Exercise capacity	2 weeks for each crossover	Exercise capacity (10.7 minutes at baseline, improved to 13.9 minutes with verapamil vs 12.3 minutes with placebo, *P* < .05)
Ahmed et al[340] DIG	NYHA I–IV; EF >45%; (*N* = 988)	Digoxin vs placebo	Primary: composite of HF hospitalization or mortality	Mean 37 months	102 (21%) in the digoxin group vs 119 (24%) in the placebo group (HR 0.82 [0.63–1.07], *P* = .136)
Pitt et al[304] TOPCAT	Symptomatic HF; EF >45%; (*N* = 3445)	Spironolactone vs placebo	Primary: composite of CV death, HF hospitalization, or aborted cardiac arrest	Mean 39 months	320 (18.6%) in the spironolactone group vs 351 (20.4%) in the placebo group (HR 0.89 [0.77–1.04], *P* = .14)
Solomon et al. PARAGON-HF[47]	HF (NYHA classes II–IV); EF >45%; (*N* = 4822)	Sacubitril-valsartan vs valsartan	Primary: composite of total HF hospitalization and CV death	Median 35 months	894 (12.8 per 100 patient-years) in the sacubitril-valsartan group vs 1009 (14.6 per 100 patient-years) in the valsartan group (HR 0.87 [0.75–1.01])
Anker et al[48] EMPEROR-Preserved	HF (NYHA classes II–IV); EF >40%; (*N* = 5988)	Empagliflozin vs placebo	Primary: composite of HF hospitalization and CV death	Median 26.2 months	415 (13.8%) in the empagliflozin group vs 511 (17.1%) in the placebo group (HR 0.79 [0.69–0.90])

BNP, B-type natriuretic peptide; CV, cardiovascular; DOE, dyspnea on exertion; EF, ejection fraction; HF, heart failure; HR, hazard ratio; METs, metabolic equivalents; MI, myocardial infarction; NA, not available; NYHA, New York Heart Association; QoL; quality of life; SBP, systolic blood pressure.

Factors affecting HF control, such as adherence to medication and diet, including NSAID and herbal remedy use, should be appropriately managed along with drug therapy. Symptomatic HFpEF is initially treated similar to other forms of HF, by slow diuresis. Diuresis decreases preload and lessens passive congestion

of the ventricles. Excessive lowering of ventricular filling pressures, however, can decrease CO and cause hypotension.

The most common cause of HFpEF is HTN that leads to LVH and decreased cardiac compliance.[299] The ACC/AHA/HFSA guidelines recommend an SBP goal of <130 mm Hg in patients with HFpEF and persistent HTN after management of fluid overload. Drugs that cause regression of LVH (eg, ACEIs, ARBs, β-blockers) may also slow or reverse structural abnormalities associated with HFpEF.

In the *P*erindopril in *E*lderly *P*atients with *C*hronic *H*eart *F*ailure (PEP-CHF) trial,[300] the ACEI perindopril failed to reduce the incidence of the primary end point (all-cause mortality or HF hospitalizations) but did reduce symptoms and improved functional capacity. The CHARM-Preserved trial[155] also failed to show any difference in CV mortality, but fewer hospitalizations were seen in the candesartan group (see Case 14-1, Question 13).

The *VAL*sartan *I*n *D*iastolic *D*ysfunction (VALIDD)[301] trial compared the effects of valsartan or placebo added to standard antihypertensive therapy (which included diuretics, β-blockers, CCBs, or α-blockers) in patients with mild HTN and diastolic dysfunction. The hypothesis of this trial was that RAAS inhibition with an ARB would be associated with greater improvement in diastolic function because of more regression of LVH or myocardial fibrosis. Patients with a history of stage 1 or 2 essential HTN were randomly assigned to receive either valsartan 160 mg, titrated up to 320 mg, or matching placebo. Patients who did not achieve a target BP goal of <135/80 mm Hg received additional therapy starting with a diuretic followed by a CCB or a β-blocker, and then an α-blocker. ARBs, ACEIs, and aldosterone blockers were excluded. The primary end point was the change in diastolic myocardial relaxation velocity from baseline to 9 months with a secondary end point of change in LV mass. During the study, the placebo group received more concomitant antihypertensive therapy compared with the valsartan group. A small, but significant, increase was seen in diastolic relaxation velocity in both groups from baseline to follow-up, but there was no significant difference between the treatment groups. BP reduction did not differ significantly between the two treatment

groups and was associated with significant improvement in diastolic function. The authors concluded that aggressive BP control—even in mild HTN—was associated with improvement in diastolic dysfunction, irrespective of whether BP reduction was achieved with a RAAS inhibitor or another antihypertensive agent.

CHARM-Preserved[155] investigated the role of candesartan in patients with HFpEF. The trial enrolled 3023 subjects who met the overall CHARM trial inclusion criteria with an EF of >40% (mean, 54%). Subjects had symptomatic HF with normal (preserved) EF. They received either an ARB alone (*N* = 1514) or placebo; only 20% of subjects in both groups were taking an ACEI at randomization, 56% a β-blocker, and 11% spironolactone.[155] After a median follow-up of 36.6 months, a trend was noted toward reduction in the primary outcome of CV death or hospital admission for HF in the candesartan group (22%) compared with placebo (24.3%; *P* = .118). CV deaths and all-cause mortality were nearly identical in both groups, but the total number of hospitalizations for HF was significantly reduced in the candesartan group. The most common side effects with candesartan were hypotension (2.4%), increase in creatinine (4.8%), and hyperkalemia (1.5%). Discontinuation because of an adverse event occurred in 17.8% of those treated with candesartan compared with 13.5% of placebo recipients (*P* = .001) (see **Table 14-14**). Overall, in symptomatic patients with HFpEF, no significant improvement in mortality occurred with candesartan compared with placebo, but there was a significant reduction in HF-related hospitalizations.

Irbesartan in Heart Failure with Preserved Ejection Fraction (I-PRESERVE) evaluated irbesartan titrated to 300 mg daily or placebo for the management of HFpEF.[302] The patient population was age 60 years or older with NYHA classes II through IV symptoms, EF of at least 45%, and hospitalized for HF within 6 months prior, or have persistent class III or IV symptoms (*N* = 4128). There was no difference in the primary end point (death from any cause or hospitalization for a CV cause) between irbesartan (36%) and placebo (37%). The irbesartan group had more patients experiencing hyperkalemia than had those on placebo. One possible reason for

the neutral results of I-PRESERVE included the high rate of dual RAAS blockade at baseline (39% ACEI use in the irbesartan group and 40% in the placebo group; 28% spironolactone use in the irbesartan group and 29% in the placebo group). Based on this high use, the study is less likely to find benefit with ARBs in addition to other RAAS agents. Another potential limitation of the study included the high study discontinuation rate (34%). Overall, irbesartan showed no benefit in reducing morbidity or mortality in patients with HFpEF.

β-Blockers or non-dihydropyridine CCBs are other classes of drugs of interest in HFpEF. Part of their value is to control HTN, a risk factor for all forms of HF. More specific to HFpEF, β-blockers and CCBs (especially verapamil) possess negative inotropic properties that may favorably influence the pathophysiology of diastolic dysfunction by (a) slowing the HR to allow more time for complete ventricular filling, particularly during exercise; (b) reducing myocardial oxygen demand; and (c) controlling BP. Both pharmacologic classes are beneficial in decreasing ischemia in patients with CAD.

Most HF trials with β-blockers demonstrating decreased morbidity and mortality have focused on HFrEF. The *S*tudy of the *E*ffects of *N*ebivolol *I*ntervention on *O*utcomes and *R*ehospitalization in *S*eniors with heart failure (SENIORS) study[303] evaluated β-blocker use in elderly patients with HF irrespective of LV function. The trial randomly assigned patients to nebivolol or placebo. Nebivolol is a selective β_1-adrenergic receptor blocker with vasodilator properties that are mediated through NO release. This effect may be beneficial in elderly patients who tend to have low reserves of endothelial vasodilation.

The primary end point of the study was the combination of all-cause mortality and CV hospital admissions. The end point was significantly reduced by 14% in the nebivolol group, regardless of the EF. Prospective subgroup analyses of the primary outcome by LVEF (≤35% or >35%), sex, or age (75 years or younger, or older than 75 years) showed benefits across all subgroups. Patients with EF

>35%, however, appeared to benefit a little more than did those with low EF%, and all-cause mortality was lower in patients older than 75 years treated with nebivolol compared with placebo. The study reinforces the current recommendations that all patients with HF with reduced EF should receive β-blockers. Only 35% of the patients had preserved LV function and were mostly males. This is not typical of patients with HFpEF, who are frequently females. Further studies are required to define the role of β-blockers in HFpEF.

No randomized controlled trials have demonstrated mortality benefits with CCBs in HFpEF. Non-dihydropyridine CCBs can be used in patients who have a contraindication to β-blockers to control BP and HR. Non-dihydropyridine CCBs should not be used in patients with HFrEF.

The role of AAs in the management of patients with HFpEF has been evaluated in the *T*reatment *O*f *P*reserved *C*ardiac function heart failure with an *A*ldosterone an*T*agonist (TOPCAT) trial.[304] This trial evaluated the impact of spironolactone versus placebo on CV morbidity and mortality in patients older than 50 years of age with an EF >45%. There was no difference in the primary end point (composite of CV death, aborted cardiac arrest, and hospitalization for HF) between the spironolactone and placebo treatment arms with an HR of 0.89 (95% CI 0.77–1.04; *P* = .14). There was a significant reduction with spironolactone versus placebo in the secondary end point of hospitalization for HF (HR 0.83 [95% CI 0.69–0.99; *P* = .04]). There has also been a subanalysis of the TOPCAT study evaluating differences in patients enrolled in the Americas compared to Russia/Georgia relative to the primary and secondary end points. When looking only at patients enrolled from North or South America, there was a significant reduction in the patients treated with spironolactone compared to those on placebo in the primary end point (HR 0.82 [95% CI 0.69–0.98]) and all secondary end points.[305] Based on these findings, the 2017 ACC/AHA/HFSA Focused Update recommend aldosterone receptor antagonists (class IIb) in HFrEF. An aldosterone receptor antagonist can be considered to decrease hospitalizations in patients with EF ≥ 45%, an elevated BNP, or recent hospitalizations. If spironolactone is initiated, then potassium

and renal function should be closely monitored (eGFR >30 mL/minute, creatinine, 2.5 mg/dL, potassium <5.0 mEq/L).[45]

The role of angiotensin–neprilysin inhibitors in the management of patients with HFpEF has been evaluated in the PARAGON-HF trial.[47] This trial evaluated the impact of sacubitril-valsartan versus valsartan along with HF hospitalizations and CV mortality in patients with NYHA classes II to IV HF and an EF of ≥45%. Patients needed to have elevated levels of NPs and have structural heart disease to be enrolled. Patients were enrolled for a median of 35 months. There were 894 primary outcomes in the sacubitril/valsartan group and 1009 primary outcomes in the valsartan arm, demonstrating a nonsignificant difference between groups (RR 0.75 [95% CI 0.75–1.10]). The two components of the primary outcome were also not statistically significant when evaluated individually. The findings of this trial demonstrate there was no difference in outcomes between sacubitril/valsartan and valsartan in the overall patient population with HFpEF; but based on the subgroup of patients[63] with an EF below normal, yet not reaching the definition of HFrEF, the FDA approved sacubitril-valsartan for use in the population with HFpEF.

The role of SGLT2 inhibitors in the management of patients with HFpEF has been evaluated in the *EMP*agliflozin outcom*E* t*R*ial in patients with chr*O*nic hea*R*t failure with *P*reserved ejection fraction (EMPEROR-Preserved) trial.[48] This trial evaluated the impact of empagliflozin versus placebo on HF hospitalizations and CV mortality in patients with NYHA classes II to IV HF and an EF of ≥40%. Patients needed to have an elevated NT-proBNP of >300 pg/mL, or if having AF, it needed to be >900 pg/mL. Patients were enrolled for a median of 26.2 months. There were 415 primary outcomes in the empagliflozin group and 511 primary outcomes in the placebo arm, demonstrating a significant difference between groups (HR 0.79 [95% CI 0.69–0.90]). The positive findings in the primary outcome were driven by the lower risk of HF hospitalizations (HR 0.71 [95% CI 0.60–0.83]). The findings of this trial demonstrate a lowering of the composite of morbidity and mortality compared to placebo in patients with HFpEF. Based on these findings, the FDA

has given empagliflozin a breakthrough designation as an investigational treatment for adults with HFpEF.

Both nitrates and PDE type 5 inhibitors have not demonstrated benefit in patients with HFpEF and thus are not recommended for use in the ACC/AHA guidelines. The lack of benefit seen with isosorbide mononitrate was demonstrated in the Nitrate's Effect on Activity Tolerance in Heart Failure with Preserved Ejection Fraction (NEAT-HFpEF) trial.[306] This trial included patients older than age 50 years with NYHA classes II to III HF and an EF of 50% or higher. The isosorbide mononitrate 120 mg group versus placebo demonstrated a nonsignificant lower daily activity level (−381 accelerometer units; 95% CI −780–17; p = .06) and a significant decrease in hours of activity per day (−0.3 hours; 95% CI −0.55 to −0.05; P = .02). Sildenafil was evaluated in the Phosphodiesterase-5 Inhibition to Improve Clinical Status and Exercise Capacity in Heart Failure with Preserved Ejection Fraction (RELAX) trial.[307] This trial included patients with NYHA classes II to III HF with an EF of ≥50% and a mean age of 69 years. The trial lasted for 24 weeks and demonstrated no significant difference between the groups in primary end point of peak oxygen consumption or the secondary end points of clinical status rank score and exercise tolerance. Based on these findings, it is not recommended to use nitrates or PDE 5 inhibitors for treating patients with HFpEF.

D.F. fulfills the criteria for having HFpEF, based on her history of long-standing HTN, which has been poorly controlled. Her BP is not at goal, and her HR is elevated. Therefore, antihypertensive therapy is warranted. Tachycardia alone can compromise the ventricle filling time and cause myocardial ischemia. So far, no data support the use of one agent over another for BP control in HFpEF. β-Blockers and non-dihydropyridine CCBs can each reduce BP and HR. β-Blockers are not considered first-line antihypertensive medications based on recent guidelines without a compelling indication. The use of a non-dihydropyridine CCB would be supported in patients with HFpEF to reduce both BP and HR. D.F. can be started on a non-dihydropyridine CCB such as diltiazem sustained release (120 mg daily).

Herbal Products and Nutritional Supplements

CASE 14-9

QUESTION 1: W.L., a 60-year-old male recently diagnosed by his naturopath with HF, is concerned about his decreasing exercise capacity and increasing SOB during his morning walks. The naturopath wants to initiate hawthorn and coenzyme Q10 to control his HF symptoms. The patient has uncontrolled HTN (170/85 mm Hg) and has 2+ ankle edema. He distrusts medical doctors because in the past he was given HCTZ for BP reduction but stopped taking it after a few days because he did not tolerate the urinary urgency it caused.

What is the role of herbal products and nutritional supplements in HF?

HAWTHORN

Hawthorn extracts from the leaves and flowers of *Crataegus monogyna* and *C. oxyacantha* have been reported to have beneficial effects in mild HF.[308,309] Oligomeric procyanidins and flavonoids are considered the key active ingredients. Hawthorn extracts have shown positive inotropic effects, weak ACE inhibition, vasodilating properties, and increased coronary blood flow in vitro and in animal models. In short-term (≤8 weeks), placebo-controlled trials in patients with the equivalent of NYHA class II HF, modest improvements were noted in exercise tolerance and subjective symptoms as well as decreases in HR and BP. Patients with more advanced HF were excluded. A systematic review by Pittler et al also concluded that hawthorn extract was efficacious in the treatment of HF when given with standard HF therapy.[310] Conversely, the results of the Hawthorne Extract Randomized Blinded Chronic Heart Failure (HERB-CHF) trial failed to provide any evidence that hawthorn was beneficial in patients with HF who were already receiving standard medical therapy.[311] In clinical trials, side effects of hawthorn include nausea, vomiting, diarrhea, palpitations, chest pain, and vertigo. These side effects are more common when doses exceed 900 mg/day, but, in some trials, they have not occurred more often than with placebo. The risks and benefits of using hawthorn and digoxin

together, both of which have positive inotropic effects, are not known.

To further investigate the longer term benefits of hawthorn, additive effects to conventional therapy and effect on mortality were tested in the Survival and Prognosis: Investigation of Crataegus Extract WS 1442 in Congestive Heart Failure (SPICE) trial.[312] The trial enrolled 2681 patients with NYHA class II or III, LVEF of ≤35%, who were randomly assigned to hawthorn or placebo for 2 years. Although the study failed to show any clear benefits in the treatment of chronic HF, hawthorn was well tolerated.

COENZYME Q

Coenzyme Q, also known as ubiquinone and ubidecarenone, is an endogenously synthesized provitamin that is structurally similar to vitamin E, serves as a lipid-soluble electron transport carrier in mitochondria, and aids in the synthesis of adenosine triphosphate.[313,314] It may also have membrane-stabilizing properties, may enhance the antioxidant effects of vitamin E, and stabilize calcium-dependent slow channels. In animal models, it has positive inotropic effects, although weaker than those of digoxin. More than 18 open-label and double-blind, randomized clinical trials have been conducted of coenzyme Q in patients with HF ranging from NYHA classes II to IV.[313] Doses varied from 50 to 200 mg/day. Patients in many of these trials were also taking diuretics, ACEIs, and digoxin. Different trials used different end point measurements. Positive effects on subjective symptoms, NYHA class improvement, EF, quality of life, and hospitalization rates have all been observed. Two trials, however, failed to demonstrate significant changes in EF, vascular resistance, or exercise tolerance. None of the trials had sufficiently large sample sizes or adequate duration of assessment to detect reduction in mortality. Side effects were minimal, but included nausea, epigastric pain, diarrhea, heartburn, and appetite suppression. Mild increases in lactate dehydrogenase and hepatic enzymes have been rarely reported with coenzyme Q doses in excess of 300 mg/day.

Because no clinical trials have demonstrated improved survival with nutritional/herbal supplements, the current guidelines do not recommend these agents in patients with current or prior symptoms of HFrEF.

W.L. has poorly controlled systolic HTN and HF that is beginning to interfere with his activities of daily life. Although evidence indicates that patients with NYHA class II HF obtain symptomatic improvement with hawthorn and coenzyme Q, this does not address W.L.'s HTN. Conflicting data exist on the value of coenzyme Q in lowering BP.[313] The results of the SPICE trial did not demonstrate any mortality benefits, and no incremental benefits were seen when combined with standard therapy. Uncontrolled HTN in patients with HF leads to cardiac remodeling and worsening HF. Currently, W.L. is presenting with symptomatic HF; therefore, he should be started on a diuretic to alleviate his symptoms. Starting with a 20-mg dose of furosemide and titrating slowly may be one approach. For all of the reasons cited throughout this chapter, one must also argue strongly for starting an ACEI to control his HTN. He should be counseled that the urinary frequency he experienced previously should diminish after a few days. Once he is euvolemic, a β-blocker should be started.

The guidelines clearly state that natural products should not be used to treat symptomatic HF. Agents such as ephedra (which contain catecholamines), ephedrine metabolites, or imported Chinese herbs are contraindicated in HF because of increased risk of mortality and morbidity. No regulatory oversight, quality control, or regulations exist on the use of natural supplements. Because of the widespread use of nutritional supplements and herbal therapies and their potential to cause drug interactions, clinicians should routinely inquire about their use.

Cardiac Arrhythmias

C. Michael White and James S. Kalus

CORE PRINCIPLES		CHAPTER CASES
ATRIAL FIBRILLATION (AF)/FLUTTER		
1	Chest palpitations, light-headedness, and reduced exercise tolerance are the most common symptoms of AF, but stroke is among the severe complications. The goals of therapy are to control the ventricular rate and reduce the risk of stroke.	**Case 15-1 (Questions 1, 2)**
2	Digoxin, β-blockers, and nondihydropyridine calcium channel blockers are appropriate rate-controlling medications. Digoxin is usually adjunctive therapy. Antiarrhythmic drugs are recommended in patients with symptoms but not needed in	**Case 15-1 (Questions 3–7)**

	asymptomatic patients (no symptoms other than palpitations).	
3	Before converting AF to sinus rhythm, assurance of a lack of clot is important but not required if someone is unconscious or hemodynamically unstable. Males with a CHA_2DS_2-VASc score of ≥2 and females with a CHA_2DS_2-VASc score of ≥3 should receive chronic anticoagulant therapy with dabigatran, rivaroxaban, edoxaban, apixaban, or warfarin. Males with a CHA_2DS_2-VASc score of 1 and females with a CHA_2DS_2-VASc score of 2 may, but are not required to, receive chronic anticoagulant therapy.	**Case 15-1 (Questions 8, 13)**
4	Antiarrhythmic drugs convert patients out of AF 50% of the time, whereas electrical shock is successful 90% of the time. To maintain sinus rhythm after conversion, class Ib agents cannot be used, class Ic agents cannot be used in patients with structural heart disease (left ventricular hypertrophy, myocardial infarction, or heart failure), and class Ia and III agents can increase the risk of torsades de pointes. Propafenone, sotalol, dronedarone, dofetilide, and amiodarone are commonly used antiarrhythmic agents for AF.	**Case 15-1 (Questions 9–12)**
5	Atrial flutter is less common than AF, but similar rate control and antiarrhythmic	**Case 15-2 (Question 1)**

	strategies can be tried. Radiofrequency ablation can be used to terminate atrial flutter.	
	PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA (PSVT)	
1	PSVT is caused by reentry within the atrioventricular (AV) node. Palpitations and hypotension can occur. The Valsalva maneuver, adenosine, or nondihydropyridine calcium channel blockers can be used to treat arrhythmia.	**Case 15-3 (Questions 1–6)**
2	In Wolff–Parkinson–White syndrome patients with PSVT, the use of AV nodal blocking agents such as β-blockers, nondihydropyridine calcium channel blockers, and digoxin can increase the risk of cardiac arrest. Ablation can destroy the bypass tract and cure the patient.	**Case 15-4 (Questions 1, 2)**
	AV BLOCK	
1	β-Blockers, digoxin, and nondihydropyridine calcium channel blockers should be withheld in patients with type 1 second- or third-degree AV block. Atropine or β-agonists (isoproterenol, dobutamine, and epinephrine) can be used acutely to treat symptomatic occurrences.	**Case 15-5 (Questions 1, 2)**
	VENTRICULAR ARRHYTHMIAS	
1	In patients with premature ventricular complexes (PVCs) or nonsustained	**Case 15-6 (Questions 1–3)**

	ventricular tachycardia (VT) and postmyocardial infarction, β-blockers are the treatment of choice. Catheter ablation is recommended for those with a high PVC burden, and all patients should be evaluated to determine whether they should receive an implantable cardioverter-defibrillator (ICD).	
2	Patients with sustained VT should be acutely treated with intravenous antiarrhythmic agents unless they are hemodynamically unstable, in which case they should be electrically converted. To prevent death from arrhythmia recurrence, ICDs are superior to antiarrhythmic drugs. To decrease the occurrence of painful ICD shocks, antiarrhythmic drugs are first-line interventions with catheter ablation for treatment failures.	**Case 15-7 (Questions 1–4)**
TORSADES DE POINTES (TdP)		
1	TdP occurs secondary to drug-induced QTc interval prolongation. Class Ia and III antiarrhythmics, antipsychotics, citalopram, fluoroquinolones, macrolides, azole antifungals, and certain opioids (methadone, kratom, mega-dose loperamide) can prolong the QTc interval. Magnesium is the treatment of choice for hemodynamically stable TdP with electrical cardioversion reserved for the	**Case 15-8 (Questions 1–4)**

	hemodynamically unstable. Naloxone does not treat opioid-induced TdP.	
CARDIAC ARREST		
1	If electrical cardioversion fails to convert ventricular fibrillation (VF), epinephrine is used to lower the defibrillation threshold and, if that fails, amiodarone is used to hold the patient in a perfusing rhythm. You never shock pulseless electrical activity or asystole but can use epinephrine.	**Case 15-9 (Questions 1–4)** **Case 15-10 (Questions 1, 2)** **Case 15-11 (Questions 1, 2)**

INTRODUCTION

Adequate circulation depends on continuous, well-coordinated electrical activity within the heart. This chapter reviews and discusses cardiac electrophysiology, arrhythmogenesis, common arrhythmias, and antiarrhythmic treatment.

ELECTROPHYSIOLOGY

Understanding Electrophysiology

CELLULAR ELECTROPHYSIOLOGY

An electrical potential exists across the cell membrane, and the electrical potential changes in a cyclic manner that is related to the flux of K^+, Na^+, and Ca^{2+} ions across the cell membrane.[1] If the change in the membrane potential is plotted against time in a given cycle of a His–Purkinje fiber, a typical action potential results (**Fig. 15-1**).

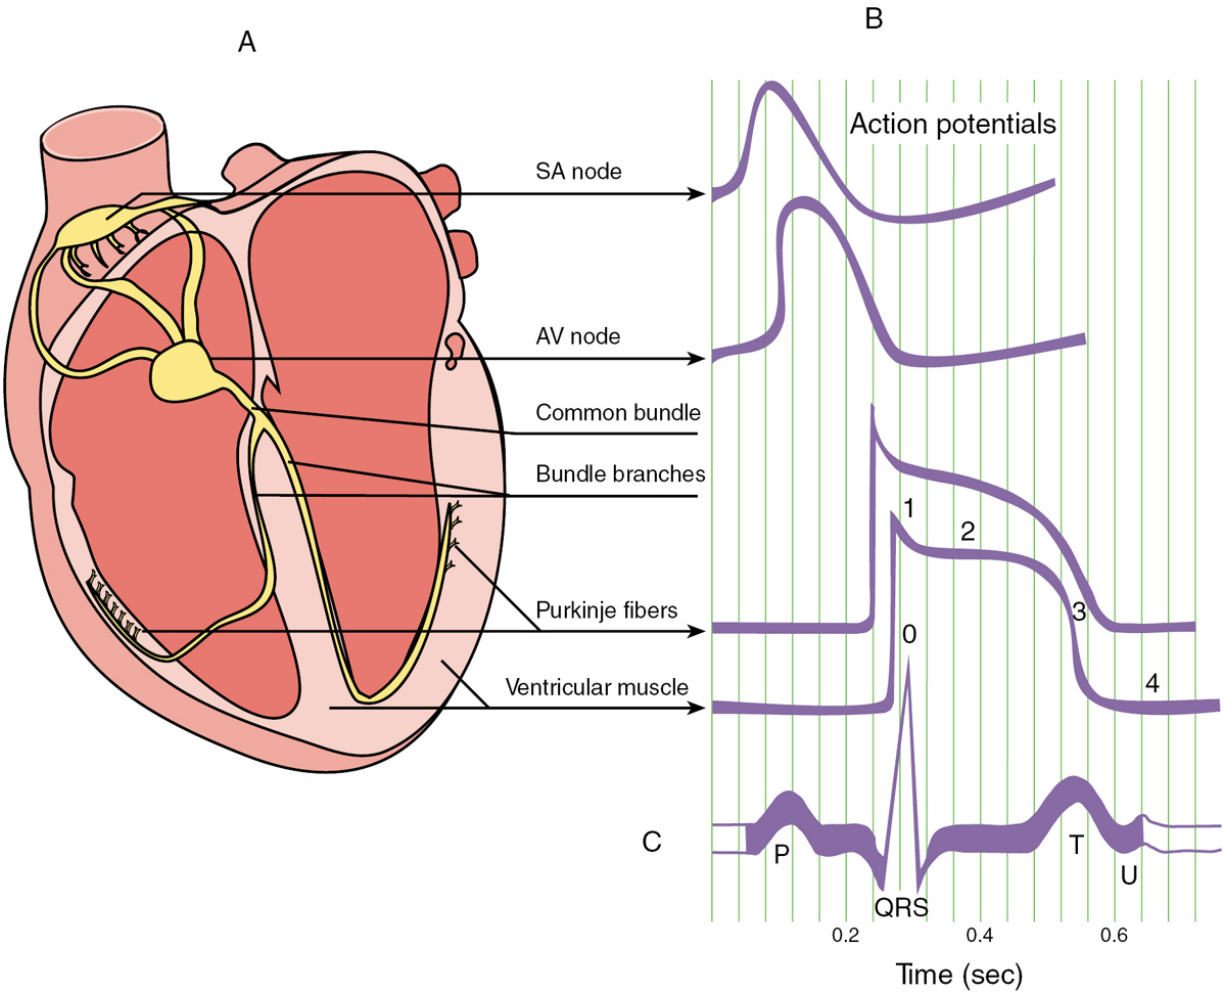

Figure 15-1 The cardiac conduction system. A, Cardiac conduction system anatomy. B, Action potentials of specific cardiac cells. C, Relationship of surface electrocardiogram to the action potential. AV, atrioventricular; SA, sinoatrial.

The action potential can be described in five phases.[1] Phase 0 is related to ventricular depolarization resulting from sodium entry into the cell through fast sodium channels. On a surface electrocardiogram (ECG), phase 0 is represented by the QRS complex. Phase 1 is the overshoot phase in which calcium enters the cell and contraction occurs. During phase 2, the plateau phase, inward depolarizing currents through slow sodium and calcium channels are counterbalanced by outward repolarizing potassium currents. Phase 3 constitutes repolarization, which on the ECG is represented by the T wave. During phase 4, sodium moves out of

the cell, and potassium moves into the cell via an active pumping mechanism. During this phase, the action potential remains flat in some cells (eg, ventricular muscle) and does not change until it receives an impulse from above. In other cells (eg, sinoatrial [SA] node), the cell slowly depolarizes until it reaches the threshold potential and again spontaneously depolarizes (phase 0). The shape of the action potential depends on the location of the cell (see Fig. 15-1). In both the SA and atrioventricular (AV) nodes, the cells are more dependent on calcium influx than sodium influx, resulting in a less negative resting membrane potential, a slow rise of phase 0, and the capability of spontaneous (automatic) phase 4 depolarization (Fig. 15-1).

The upward slope of phase 0, referred to as V_{max}, is related to the conduction velocity. The steeper the slope, the more rapid is the rate of depolarization. Another influence on V_{max} is the point at which depolarization occurs. The less negative the threshold potential, the slower V_{max} will be, and hence conduction velocity is slowed. Drugs can affect V_{max} and conduction velocity by blocking the fast sodium channels or by making the resting membrane potential less negative (eg, class I agents).

The action potential duration (APD) is the length of time from phase 0 to the end of phase 3. The effective refractory period is the length of time that the cell is refractory and will not propagate another impulse. Both of these measurements can be obtained from intracardiac recordings of the action potential. Class Ia and III agents prolong the refractoriness of the heart.[1]

NORMAL CARDIAC ELECTROPHYSIOLOGY

Automaticity

Automaticity is the ability of cells (often called pacemaker cells) to depolarize spontaneously. These cells are located in the SA and AV nodes and the His-Purkinje system. The SA node is normally the dominant pacemaker because it reaches the threshold faster than other nodes in a normal heart, resulting in 60 to 100 depolarizations per minute.[2] The innate AV node and Purkinje rate of depolarization

are 40 to 60 and 40 depolarizations per minute, respectively. In the healthy heart, the AV node and Purkinje fibers are prevented (overridden) from spontaneous depolarization by the more frequent impulses from the SA node.

Conduction

An impulse normally originates in the SA node and travels down specialized intranodal pathways to activate atrial muscle and the AV node. The AV node holds the impulse briefly before releasing it to the bundle of His. It then travels to the right and left bundle branches and out to the ventricular myocardium via the Purkinje fibers. The ECG tracing consists of a series of complexes that correspond to electrical activity in a specific location or anatomic site. By convention, these electrical deflections have been labeled the P wave, QRS complex, and T wave. The P wave represents depolarization of the atria, whereas the QRS complex reflects ventricular depolarization. The T wave reflects repolarization of the ventricles. To evaluate the intact conduction system, conduction intervals at different sites can be obtained. The normal intervals as measured by ECG or intracardiac electrodes are shown in **Table 15-1**. Drugs and ischemia can alter the conduction and hence the ECG intervals. The effects of antiarrhythmic agents on the ECG are described in **Table 15-2**.

Table 15-1

Normal Electrocardiographic Intervals

Interval	Normal Indices (milliseconds)	Electrical Activity
PR	120–200	Atrial depolarization
QRS	<140	Ventricular depolarization
QTc[a]	<400	Ventricular repolarization

[a]QTc interval is the QT interval corrected for heart rate.

Table 15-2

Pharmacologic Properties of Antiarrhythmic Agents

	Surface ECG				
Type	PR Interval	QRS Interval	QT Interval	Conduction Velocity	Refractory Period
Ia	0/↑	↑	↑↑	↑↓[a]	↑[b]
Ib	0	0	0	0/↓	↓[b]
Ic	↑	↑↑	↑	↑[b]	0[b]
II	↑↑	0	0	↓[b]	↑[b]
III	0[c]	0	↑↑	0[b]	↑[b]
IV	↑↑	0	0	↓[b]	↑[b]

ECG, electrocardiogram.

[a]Conduction increases at low dosages and decreases at higher dosages.

[b]On atrial and atrioventricular nodal tissue.

[c]May cause PR prolongation independent of class III antiarrhythmic activity.

Pathophysiology

ABNORMAL IMPULSE FORMATION

Abnormal impulse formation can arise from abnormal automaticity or triggered activity originating from the SA node (eg, sinus bradycardia) or other sites (eg, junctional or idioventricular tachycardia). Causes of abnormal automaticity include hypoxia, ischemia, or excess catecholamine activity.

Triggered activity occurs when there is an attempted depolarization before or after the cell is fully repolarized, but not by a pacemaker cell. These after-depolarizations may occur in phase 2 or 3 (early) or phase 4 (delayed) of the action potential. Early after-depolarizations (EADs) arise from a reduced level of membrane potential and may require a bradycardic state. Torsades de pointes (TdP), a form of polymorphic ventricular tachycardia (VT), is thought to be initiated by EAD. Delayed after-depolarizations, often seen with

digoxin toxicity, are thought to be secondary to an overload of intracellular free calcium.

ABNORMAL IMPULSE CONDUCTION

Reentry

The most common abnormal conduction leading to arrhythmogenesis is reentry. A reentrant circuit is formed as normal conduction occurs down a pathway that bifurcates into two pathways (eg, AV node or left and right bundle branches). The impulse travels along one pathway (**Fig. 15-2**) but encounters unidirectional antegrade block in the other pathway (see Fig. 15-2). The impulse that passed through the unblocked pathway propagates in a retrograde manner (ie, moves backward) through the previously blocked pathway. This abnormal impulse can travel down the first pathway again when it is not refractory. Supraventricular and monomorphic VT are both examples of reentrant arrhythmias.

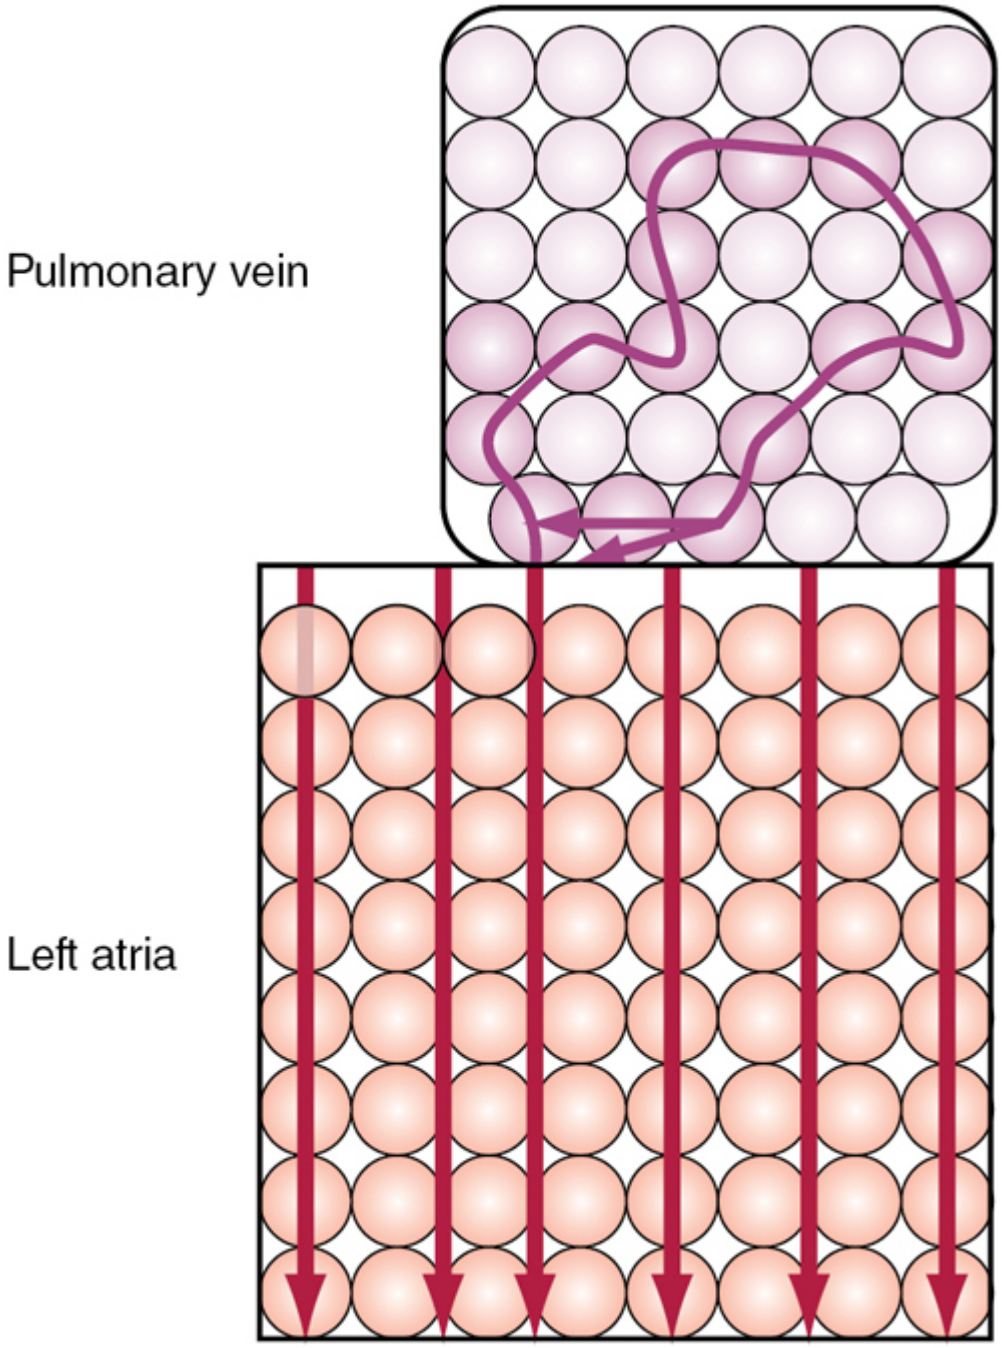

Figure 15-2 Reentrant circuit in the pulmonary vein. In the pulmonary vein, there is a mixing of electrically active cells (*shaded circles*) and electrically inactive cells (*white circles*). Although the main wave of depolarization goes homogenously down the atria, a small depolarization stimulus enters the pulmonary vein and meanders through the electrically active tissue. In this case, there is a reentrant circuit formed where the impulse can continue to rotate

through the pulmonary vein and a route for it to stimulate the atria as well.

Block

Another form of abnormal impulse conduction occurs when the normal conducting pathway is blocked and the impulse is forced to travel through nonpathway tissues to cause depolarization. Common examples are left and right bundle branch blocks in the ventricles. A block in one path necessitates retrograde conduction through the opposite bundle to stimulate both ventricles. Nonpathway tissue conducts the electrical impulse more slowly than conduction tissues do.[1]

Classification of Arrhythmias

All arrhythmias originating above the bundle of His are referred to as supraventricular arrhythmias. These may include sinus bradycardia, sinus tachycardia, paroxysmal supraventricular tachycardia (PSVT), atrial flutter, atrial fibrillation (AF), Wolff–Parkinson–White (WPW) syndrome, and premature atrial contractions (PACs). All of these arrhythmias are characterized by normal QRS complexes (ie, normal ventricular depolarization) unless there is a bundle branch block. Not all these rhythm changes are necessarily a sign of pathology. For example, athletes with a well-conditioned heart and large stroke volume commonly have slow heart rates (sinus bradycardia). Vigorous exercise is accompanied by transient sinus tachycardia.

Arrhythmias originating below the bundle of His are referred to as ventricular arrhythmias. These include premature ventricular contractions (PVCs), VT, and ventricular fibrillation (VF). Conduction blocks often are categorized separately based on their level or location, which can be a supraventricular site (eg, first-, second-, or third-degree AV block, see Case 15-6, Question 2) or in the ventricle (eg, right or left bundle branch block). An alternative method of classifying arrhythmias is based on the rate: bradyarrhythmia (<60 beats/minute) or tachyarrhythmia (>100 beats/minute). There is a

website with useful rhythm evaluation tutorials at http://www.blaufuss.org.

Antiarrhythmic Drugs

Based on their electrophysiologic (EP) and pharmacologic effects, there are four Vaughn-Williams antiarrhythmic drug classes. Class I drugs, sodium channel blockers, are subdivided further depending on the duration of blockade (class Ia: intermediate; Ib: fast; and Ic: long). Class II drugs are β-adrenergic blockers, class III drugs are potassium channel blockers, and class IV drugs are calcium channel blockers. The classification, pharmacokinetics, and adverse effects of these agents are summarized in **Table 15-3**.

Table 15-3
Vaughn-Williams Classification of Antiarrhythmic Agents

Drug and Classification	Pharmacokinetics	Indications	Side Effects
Class Ia (can cause torsades de pointes similar to class III agents)			
Quinidine sulfate (83% quinidine; SR) Quinidine gluconate (62% quinidine; SR)	$t_{1/2}$ = 6.2 ± 1.8 hours (affected by age, cirrhosis); V_d = 2.7 L/kg (↓ in HF); liver metabolism, 80%; renal clearance, 20%; C_p = 2–6 μg/mL, CYP3A4 substrate, CYP2D6 inhibitor, P-glycoprotein inhibitor	AF (conversion or prophylaxis), WPW, PVCs, VT	Diarrhea, hypotension, N/V, cinchonism, fever, thrombocytopenia, proarrhythmia
Procainamide	$t_{1/2}$ = 3 ± 0.6 hours; V_d = 1.9 ± 0.3 L/kg; liver metabolism 40%; renal clearance (GFR + possible CTS) 60%; active metabolite (NAPA)[a] C_p = 4–10 μg/mL, possible CTS substrate	AF (conversion or prophylaxis), WPW, PVCs, VT	Hypotension, fever, agranulocytosis, SLE (joint/muscle pain, rash, pericarditis), headache, proarrhythmia
Disopyramide (SR and CR forms)	$t_{1/2}$ = 6 ± 1 hours; V_d = 0.59 ± 0.15 L/kg; liver metabolism, 30%; renal clearance, 70%; C_p = 3–6 μg/mL	AF, WPW, PSVT, PVCs, VT	Anticholinergic (dry mouth, blurred vision, urinary retention), HF, proarrhythmia
Class Ib[b] (cannot be used to treat atrial arrhythmias)			
Lidocaine	$t_{1/2}$ = 1.8 ± 0.4 hours; V_d = 1.1 ± 0.4 L/kg; liver metabolism, 100%; C_p = 1.5–6 μg/mL	PVCs, VT, VF	Drowsiness, agitation, muscle twitching, seizures, paresthesias, proarrhythmia
Mexiletine	$t_{1/2}$ = 10.4 ± 2.8 hours; V_d = 9.5 ± 3.4 L/kg; liver metabolism, 35%–80%; C_p = 0.5–2 μg/mL	PVCs, VT, VF	Drowsiness, agitation, muscle twitching, seizures, paresthesias, proarrhythmia, N/V, diarrhea
Class Ic (cannot be used in patients with structural heart disease)			
Flecainide	$t_{1/2}$ = 12–27 hours; CYP2D6 substrate, 75%; renal clearance, 25%; C_p = 0.4–1 μg/mL	AF, PSVT, severe ventricular arrhythmias	Dizziness, tremor, lightheadedness, flushing, blurred vision, metallic taste, proarrhythmia
Propafenone	$t_{1/2}$ = 2 hours (extensive metabolizer); 10 hours (poor metabolizer); V_d = 2.5–4 L/kg, CYP2D6 substrate/inhibitor, P-glycoprotein inhibitor	PAF, WPW, severe ventricular arrhythmias	Dizziness, blurred vision, taste disturbances, nausea, worsening of asthma, proarrhythmia
Class III (can cause torsade de pointes similar to class Ia agents, amiodarone, and dronedarone and have lower risk)			
Amiodarone	$t_{1/2}$ = 40–60 days; V_d = 60–100 L/kg; erratic absorption; liver metabolism, 100%; oral F = 50%, C_p = 0.5–2.5 μg/mL, CYP1A2, 2D6, 2C9, 3A4 inhibitor, P-glycoprotein inhibitor	AF, PAF, PSVT, severe ventricular arrhythmias, VF	Blurred vision, corneal microdeposits, photophobia, skin discoloration, constipation, pulmonary fibrosis, ataxia, hypothyroid or hyperthyroid, hypotension, N/V
Sotalol[c]	$t_{1/2}$ = 10–20 hours; V_d = 1.2–2.4 L/kg; renal clearance, 100%	AF (prophylaxis), PSVT, severe ventricular arrhythmias	Fatigue, dizziness, dyspnea, bradycardia, proarrhythmia
Dofetilide	$t_{1/2}$ = 7.5–10 hours; V_d = 3 L/kg; renal elimination, 60% (GFR + CTS), CYP3A4 substrate	AF or atrial flutter conversion and prophylaxis	Chest pain, dizziness, headache, proarrhythmia
Ibutilide	$t_{1/2}$ = 6 (2–12) hours; V_d = 11 L/kg, C_p = undefined	AF or atrial flutter conversion	Headache, nausea, proarrhythmia
Dronedarone	$t_{1/2}$ = 13–19 hours; V_d = 20 L/kg, T_{max} = 3–6 hours, CYP3A4 substrate, CYP 2D6, 3A4 inhibitor, P-glycoprotein inhibitor, take with food for maximal absorption	AF or atrial flutter prophylaxis	Diarrhea, nausea, dermatitis or rash, bradycardia, hepatotoxicity, pregnancy category X

AF, atrial fibrillation; C_p, steady-state plasma concentration; CR, controlled release; CTS, cation tubular secretion; CYP, cytochrome P-450; F, bioavailability; GFR, glomerular filtration rate; HF, heart failure; NAPA, *N*-acetylprocainamide; N/V, nausea and vomiting; PAF, paroxysmal atrial fibrillation; PSVT, paroxysmal supraventricular tachycardia; PVC, premature ventricular contraction; SLE, systemic lupus erythematosus; SR, sustained release; $t_{1/2}$, half-life; V_d, volume of distribution; VF, ventricular fibrillation; VT, ventricular tachycardia; WPW, Wolff–Parkinson–White syndrome.

[a]NAPA is 100% renally eliminated and possesses class III antiarrhythmic activity.

[b]Phenytoin is classified as a class Ib antiarrhythmic.

[c]Possesses both class II and III antiarrhythmic activities.

Class Ia and class III antiarrhythmic agents increase repolarization time, the QTc interval, and the risk of TdP. Class II and IV antiarrhythmic agents may decrease heart rate (cause bradycardia), decrease ventricular contractility (decrease stroke volume), and prolong the PR interval (cause second- or third-degree AV block). Class Ib antiarrhythmic agents work only in ventricular tissue, so they cannot be used in AF or atrial flutter. Class Ic antiarrhythmic agents are useful but should never be used after a myocardial infarction (MI) or with heart failure with reduced ejection fraction (HFrEF) or severe left ventricular hypertrophy (classified as structural heart diseases) because increased mortality can result. These drugs are discussed in greater detail later.

SUPRAVENTRICULAR ARRHYTHMIAS

The specific arrhythmias include (a) those primarily atrial in origin, such as AF, atrial flutter, paroxysmal sinus tachycardia, ectopic atrial tachycardia, and multifocal atrial tachycardia and (b) AV nodal reentrant tachycardia (AVNRT) and AV reentrant tachycardia (AVRT) involving accessory pathways within the atria or ventricle. AVNRT and AVRT often self-terminate and are paroxysmal (episodic) in nature; thus, they are commonly referred to as PSVT. The most common supraventricular arrhythmias are AF, atrial flutter, and PSVT.

Atrial Fibrillation and Atrial Flutter

AF is usually initiated when a depolarization stimulus arising from an ectopic focus or reentrant circuit impacts the atria while the tissue is in the vulnerable period. The vulnerable period in the atria and

ventricles occurs during the first half of the QRS complex; this period is vulnerable because the net charge is near normal, but the ion concentrations of sodium, calcium, and potassium inside and outside the cells are radically different. Stimulation during the vulnerable period causes multiple ectopic foci to arise and attempt to pace the atria with no single pacemaker in control, eliminating discernable P waves on the ECG (**Fig. 15-3**) and eliciting a rapid, ineffective writhing of the atrial muscle with a classic "irregularly irregular" ventricular rate. In contrast, atrial flutter (**Fig. 15-4**) is characterized by typical sawtooth atrial waves, at a rate of 280 to 320 beats/minute, and a variable ventricular rate, depending on the nature of the AV block present (eg, 2, 3, or 4 atrial beats for each ventricular beat or 2:1, 3:1, or 4:1 block). In most cases, the ventricular rate is ~150 beats/minute. Episodes of atrial flutter can progress to AF if the ectopic atrial depolarization stimulus impacts the surrounding atrial tissue in the vulnerable period. When patients initially experience AF, the episodes are usually short lived, and spontaneous conversion occurs. The pattern of erratic initiation and termination of AF is termed paroxysmal atrial fibrillation (PAF), and if enough AF events occur in close proximity to each other, the duration of subsequent AF events increases in length and the event degenerates into persistent AF. In persistent AF, the AF episode will continue until the heart is electrically or chemically converted out of the rhythm. With time, persistent AF degenerates into permanent AF, in which normal sinus rhythm cannot be achieved and sustained. An example of PAF is presented in the following section.

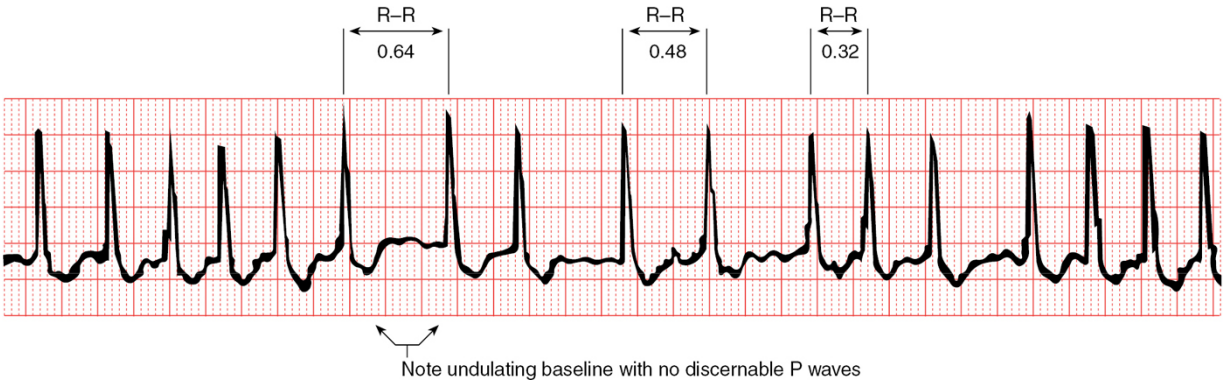

Figure 15-3 Atrial fibrillation. Note the irregularly irregular R–R intervals, undulating baseline without definitive P waves, normal width of the QRS complexes, and ventricular rate of 140 beats/min.

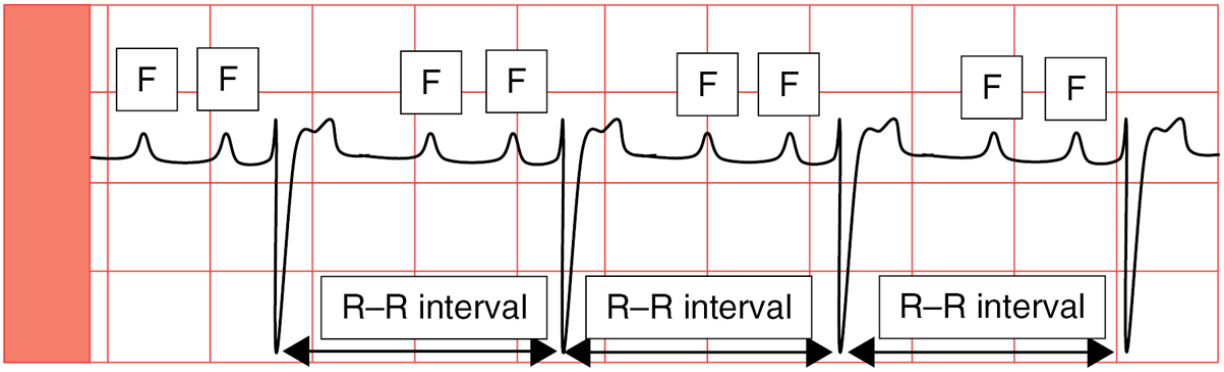

Figure 15-4 Atrial flutter. Note the sawtooth appearance of the rhythm strip. F denotes flutter waves with consistent R–R spacing.

CLINICAL MANIFESTATION AND UNDERLYING CAUSES

CASE 15-1

QUESTION 1: J.K., a 66-year-old male, presents for a routine checkup in the clinic. His medical history includes type 2 diabetes mellitus and HFrEF for the last 5 years, hypertension, and gout. There is no history of rheumatic heart disease, MI, pulmonary embolism, or thyroid disease. Medications include metformin 1 g twice daily, lisinopril 40 mg every day, furosemide 40 mg twice daily, metoprolol succinate 100 mg once daily, and allopurinol 300 mg/day. J.K. does not smoke or drink alcohol. Physical examination reveals a blood pressure (BP) of 136/84 mm Hg, pulse of 70 beats/minute in normal sinus rhythm, respiratory rate of 12 breaths/minute, and temperature of 98.2 °F (36.77 °C). His body mass index is 32 kg/m^2.

What factors in J.K.'s past medical history predispose him to the development of AF? What is his 10-year risk of developing AF?

AF is commonly associated with, or a manifestation of, other diseases or disorders (**Table 15-4**).[2,3] When treatable underlying causes are present, they should be corrected because this may resolve the AF. A risk prediction tool highlights common factors associated with the development of AF, particularly older age, male gender, hypertension, heart failure (HF), obesity, and valvular

disease.[4,5] In a small percentage of patients who do not have underlying heart disease, AF is called “lone” AF and usually has a more benign course.

Table 15-4
Causes of Atrial Fibrillation and Flutter

Alcohol	Nonrheumatic Heart Disease
Atrial septal defect	Pericarditis
Cardiac surgery	Pneumonia
Cardiomyopathy	Pulmonary embolism
Cerebrovascular accident	Sick sinus syndrome
Chronic obstructive pulmonary disease	Stimulants Thyrotoxicosis
Fever	Trauma
Hypothermia	Tumors
Ischemic heart disease	Wolff–Parkinson–White syndrome
Mitral valve disease	

J.K. has several risk factors for the development of AF within the next 10 years, including the presence of treated hypertension, HF, his age, and his sex. A detailed scoring system is described in the referenced manuscript but is beyond the scope of this chapter. Using his risk factors, his 10-year risk of developing AF would be >30%.[4]

Consequences of Atrial Fibrillation

Case 15-1, Question 2: Two years later, J.K. presents with dyspnea on exertion (DOE) and palpitations for the last 2 weeks. He experienced palpitations of shorter duration three times in the last year, but these were not associated with DOE. On physical examination, he is found to have rales. Cardiac examination reveals an irregularly irregular rhythm without murmurs, gallops, or rubs. His jugular veins are distended 4 cm, but no organomegaly is found. His extremities have 1+ pitting edema. The ECG shows AF (see Fig. 15-3), and the chest radiograph is compatible with mild pulmonary congestion. A cardiac echocardiogram reveals the atrial size to be <5 cm (normal) and a left

ventricular ejection fraction of 35%. What clinical findings demonstrated by J.K. are typically associated with AF? What are the likely consequences of his AF?

The most common issue in patients with AF, as with J.K., is palpitations (the sensation of the heart beating rapidly or unusually in the chest). This is a result of the rapid ventricular rate, which typically ranges from 100 to 160 beats/minute. The R–R interval (time from the R wave in one QRS complex to the R wave in the next complex) is irregularly irregular (random irregularity). During AF, the atrial kick or the atria's contribution to stroke volume is lost. Because the atrial kick may account for 20% to 30% of the total stroke volume, this, coupled with rapid ventricular rates and irregular R–R interval spacing during AF, can cause symptoms of inadequate blood flow such as light-headedness, dizziness, or reduced exercise tolerance. However, some patients are asymptomatic except for palpitations. Depending on the underlying ventricular function, signs of HF, such as DOE and peripheral edema, may develop, as experienced by J.K. Conversely, underlying HF may precipitate AF.

Patients with AF are at risk for thrombotic stroke (see Stroke Prevention section).[6] With the chaotic movement of the atria, normal blood flow is disrupted, and atrial mural thrombi (usually forming in a pouch called the left atrial appendage) may form. The risk of stroke increases after the restoration of normal sinus rhythm, which allows more efficient cardiac contractility and expulsion of the thrombus. Patients with nonvalvular AF have a fivefold increase in the risk of stroke; this risk increases as patients have an increased number of associated risk factors. Other concurrent diseases that may increase the risk of stroke are HF, cardiomyopathy, thyrotoxicosis, congenital heart disease, and valvular heart disease. Because of the high risk of stroke and significant impact of stroke on patient outcomes, pharmacologic stroke prophylaxis is often indicated. Selection of an appropriate antithrombotic regimen for the patient with AF must be based on the assessment of the underlying stroke and bleeding risk. Risk stratification in AF is performed with the use of the CHA_2DS_2-VASc scoring system. A CHA_2DS_2-VASc score is calculated by

assigning one point each for the presence of congestive HF, hypertension, diabetes, vascular disease, age of 65 to 74 years, or female gender and two points for the age of 75 years or older or a history of stroke. Points are totaled, and the subsequent score correlates with stroke risk.[6]

TREATMENT OF ATRIAL FIBRILLATION

Goals of therapy

CASE 15-1, QUESTION 3: What are the therapeutic goals and general approaches used to treat AF in patients like J.K.?

The two primary goals of treatment are to control the ventricular response rate and to reduce the risk of stroke. In some cases, a third therapeutic goal may be conversion to normal sinus rhythm.

Ventricular rate control

Digoxin

CASE 15-1, QUESTION 4: J.K. is given a 1-mg loading dose of digoxin, followed by a 0.25-mg every day maintenance dose. What is the purpose of administering digoxin? What are the relative advantages and disadvantages of digoxin compared with other agents to control ventricular rate?

The first treatment goal is to slow the ventricular response rate, which allows better ventricular filling with blood. **Table 15-5** displays the agents commonly used to control the ventricular response and provides typical loading and maintenance doses. Because of its direct AV node-blocking effects and vagomimetic properties, digoxin prolongs the effective refractory period of the AV node and reduces the number of impulses conducted through the AV node (negative dromotropy).[6–8]

Table 15-5
Agents Used for Controlling Ventricular Rate in

Supraventricular Tachycardias[a]

Drug	Loading Dose	Usual Maintenance Dose	Comments
Digoxin	10–15 μg/kg LBW up to 1–1.5 mg IV or PO for 24 hours (eg, 0.5 mg initially, then 0.25 mg every 6 hours)	PO: 0.125–0.5 mg/day; adjust for renal failure (see Chapter 14, Heart Failure)	Maximal response may take several hours; use with caution in patients with renal impairment.
Esmolol	0.5 mg/kg IV for 1 minute	50–300 μg/kg/minute continuous infusion with bolus between increases	Hypotension common; effects additive with digoxin and calcium channel blockers
Propranolol	0.5–1.0 mg IV repeated every 2 minutes (up to 0.1–0.15 mg/kg)	IV infusion: 0.04 mg/kg/minute PO: 10–120 mg tid	Use with caution in patients with HF or asthma; additive effects seen with digoxin and calcium channel blockers
Metoprolol	5 mg IV at 1 mg/min	PO: 25–100 mg bid	Use with caution in patients with HF or asthma; additive effects seen with digoxin and calcium channel blockers
Verapamil	5–10 mg (0.075–0.15 mg/kg) IV for 2 minutes; if response inadequate after 15–30 minutes, repeat 10 mg (up to 0.15 mg/kg)	IV infusion: 5–10 mg/hour PO: 40–120 mg tid or 120–480 mg in sustained-release form daily	Hypotension with IV route; AV blocking effects are additive with digoxin and β-blockers; may increase digoxin levels.
Diltiazem	0.25 mg/kg IV for 2 minutes; if response inadequate after 15 minutes, repeat 0.35 mg/kg for 2 minutes.	IV infusion: 5–15 mg/hour PO: 60–90 mg tid or qid or 180–360 mg in extended-release form daily	Response to IV therapy occurs in 4–5 minutes; hypotension; effects additive with digoxin and β-blockers

AV, atrioventricular; bid, two times a day; HF, heart failure; IV, intravenously; LBW, lean body weight; PO, orally; qid, four times a day; tid, three times a day.

[a]AV nodal ablation is a nonpharmacologic alternative to control the ventricular response, but the effect is permanent and may require chronic ventricular pacing afterward.

There are several limitations associated with digoxin use in AF. Digoxin has a slow onset of action. After an intravenous (IV) dose, it will take more than 2 hours for the onset of effect and 6 to 8 hours for the maximal effect, which is markedly slower than other negative dromotropic agents.[7] Digoxin is also less effective than β-blockers and nondihydropyridine calcium channel blockers during states of heightened sympathetic tone (eg, exercise or emotional stress), a common precipitant of PAF.[6–8] The 2014 American Heart Association/American College of Cardiology/Heart Rhythm Society Guidelines for the management of patients with AF recommend that digoxin use be reserved for control of ventricular response rate in patients with impaired left ventricular function or HF or for use as an add-on therapy when treatment with a β-blocker or calcium channel blocker provides inadequate rate control.[6] Patients who require rate control of AF and have a lower BP may also benefit from rate control with digoxin. It should also be noted that digoxin serum concentrations may be increased when combined with P-

glycoprotein inhibitors such as verapamil, propafenone, quinidine, flecainide, and amiodarone.[9,10] Normally, P-glycoprotein in the brush border membrane of intestinal enterocytes pumps digoxin into the lumen of the gut, reducing its bioavailability and pumps digoxin out of the body via the renal tubules (see Chapter 14, Heart Failure, for discussion of digoxin and digoxin drug interactions).

Case 15-1, Question 5: J.K. has diabetes, which increases the risk for diabetic nephropathy. Would the dosing be changed if J.K. had renal dysfunction?

J.K.'s renal function is normal. If he had significant renal dysfunction, both the loading and the maintenance doses of digoxin would need to be altered. A loading dose is used to achieve a therapeutic level, and volume of distribution of digoxin is reduced in patients with renal dysfunction. The digoxin maintenance dose is highly dependent on renal clearance because digoxin is eliminated 50% to 75% unchanged in the urine (see Chapter 14, Heart Failure, for further discussion of digoxin dosing in patients with normal and impaired renal function). Although the usual digoxin target range is generally 0.5 to 1.0 ng/mL in the management of patients with HFrEF,[11] higher serum concentrations may be necessary when using digoxin as a rate control agent for J.K.

a-Adrenergic Blocking Agents

Case 15-1, Question 6: What other drugs can be used for ventricular rate control, and what are their relative advantages and disadvantages compared with digoxin?

β-Adrenergic blocking agents are another class of negative dromotropic agents used in AF. Propranolol, metoprolol, and esmolol are available for IV administration. Each agent rapidly controls the ventricular rate both at rest and during exercise. β-Blockers are the first choice in high catecholamine states such as thyrotoxicosis and

postcardiac surgery. However, given their negative inotropic effects, β-blockers should be used cautiously to acutely control the ventricular response in patients with decompensated HFrEF. Although β-blockers are used to treat HFrEF (eg, bisoprolol, carvedilol, and metoprolol), they need to be started at low doses and titrated slowly for several weeks to therapeutic doses[2] (see Chapter 14, Heart Failure). When trying to achieve rapid rate control, more aggressive dosing may be needed. β-Blockers should also be avoided in patients with asthma because of their β_2-blocking properties, and blood glucose levels should be monitored more closely in patients with diabetes mellitus because the signs and symptoms of hypoglycemia (except sweating) can be masked.

Calcium Channel Blockers

Nondihydropyridine calcium channel blockers are also effective in slowing the ventricular rate at rest and during exercise. Both verapamil and diltiazem can be administered IV for a rapid (4–5 minutes) reduction in heart rate.[8] Nondihydropyridine calcium channel blockers should not be used in patients presenting with decompensated HF.[6] They work through their effect on slow calcium channels within the AV node. Although the duration of action produced by bolus dosing is short, both agents can be administered either as a continuous drip or orally. Given the ability of calcium channel blockers to cause arteriolar dilation, a transient decrease in BP may be seen. IV calcium pretreatment can be used to attenuate the BP decrease among patients with hypotension, near-hypotensive BP, or left ventricular dysfunction. Calcium pretreatment does not appear to diminish the negative dromotropic effects of nondihydropyridine calcium channel blockers.[12-14] Verapamil is contraindicated in patients with an ejection fraction <35%, and diltiazem should be used with caution in HFrEF. Verapamil increases the concentrations of other cardiovascular drugs such as digoxin, dofetilide, simvastatin, and lovastatin. Verapamil and diltiazem are good alternatives to β-blockers in patients with asthma.[6]

For chronic therapy, oral negative dromotropic agents (usually a β-blocker or nondihydropyridine calcium channel blocker) are recommended. If higher dose monotherapy with one of these drugs is needed to control symptoms but is associated with intolerable side effects, adding lower dose digoxin to a β-blocker or calcium channel blocker is recommended.[6,15,16]

J.K. has signs of mild HF, so digoxin is a reasonable choice, although short-term IV diltiazem is often used in this type of patient as well. IV verapamil and β-blockers may worsen the signs and symptoms of HF, and the β-blockers may mask signs of hypoglycemia in J.K. The goal of rate control should be a resting heart rate between 60 and 80 beats/minute and an exercising heart rate between 90 and 115 beats/minute.[6] A study has explored the use of a more lenient target resting heart rate (<110 beats/minute) and reported similar patient outcomes as compared with a more strict target heart rate (resting heart rate <80 beats/minute).[17] This study may suggest that it could be acceptable for a patient's heart rate to be >80 beats/minute if there is difficulty in achieving this level of heart rate control in asymptomatic patients or those with HF and a preserved EF.[6,18]

Rate Control Versus Rhythm Control

Case 15-1, Question 7: After loading of digoxin, J.K.'s heart rate is still 120 beats/minute, and he continues to experience palpitations. His BP is 100/60 mm Hg, and his symptoms of HF are improving, but he still has mild shortness of breath. The decision is made to cardiovert J.K. to normal sinus rhythm. Is J.K. a good candidate for a rhythm control strategy and if so, why? What is the likelihood that J.K. will be successfully converted to normal sinus rhythm?

The use of a rhythm control strategy has become much less common during the last several years. This change is because of the completion of several studies comparing the effect of a rate or rhythm control strategy on patient outcomes.[19–24] The AFFIRM study (Atrial Fibrillation Follow-up Investigation of Rhythm Management), a randomized, multicenter study, was one of the largest to compare

rate control with rhythm control for the management of AF. AFFIRM enrolled 4060 patients with AF and a risk of stroke.[19] The primary end point was all-cause mortality. Antiarrhythmic drugs were chosen at the discretion of the treating physician, but >60% of the patients received amiodarone or sotalol as the initial antiarrhythmic agent. Rate control agents included digoxin, β-blockers, and nondihydropyridine calcium channel blockers. After a mean follow-up of 3.5 years, there was a trend toward lower overall mortality (*P* = .08) with significant reductions in hospitalizations (10% lower; *P* = .001) and TdP (300% lower; *P* = .007) in the rate control group. Therefore, using rhythm control in patients with AF rather than rate control does not improve outcomes and increases the risk of hospitalizations and TdP.

The default long-term treatment strategy for most patients should be a rate control strategy, in which heart rate is controlled and anticoagulation is provided if indicated. However, rhythm control is necessary when patients experience symptoms despite adequate rate control, when heart rate cannot be adequately controlled with currently available treatments, or if patients cannot tolerate the adverse effects of rate-controlling medications. J.K.'s heart rate is not adequately controlled with digoxin and an oral β-blocker. It is not advisable to increase his β-blocker at this time, given that he has mild symptoms of HF decompensation. A nondihydropyridine calcium channel blocker could be added to better control his heart rate; however, his BP may not tolerate the addition of a nondihydropyridine calcium channel blocker. Therefore, the pursuit of a rhythm control strategy is warranted.

Likelihood of successful conversion to, and maintenance of, normal sinus rhythm is determined by the duration of the arrhythmia, underlying disease processes, and left atrial size.[6,25] Duration of AF for more than 1 year significantly reduces the chances of maintaining a normal sinus rhythm. When the atrial size exceeds 5 cm, there is a <10% chance of maintaining normal sinus rhythm at 6 months. J.K.'s chance of being maintained in normal sinus rhythm is good because the duration of his AF is short and the echocardiogram revealed only slight enlargement of his left atrium.

Conversion to normal sinus rhythm

Case 15-1, Question 8: Warfarin treatment is begun and J.K.'s prothrombin time is to be maintained at an international normalized ratio (INR) of 2 to 3. J.K. is scheduled for a transesophageal echocardiogram (TEE) to determine whether cardioversion can be performed during this admission. How does a TEE help to determine whether cardioversion can be performed, and why is warfarin therapy being used?

When the onset of AF is <48 hours, the likelihood of atrial clot formation is low. However, if patients are at high risk for stroke, they should receive an anticoagulant (unfractionated heparin, low-molecular-weight heparin, factor Xa, or direct thrombin inhibitor) as soon as possible surrounding the cardioversion, followed by long-term anticoagulation.[6] When the duration of AF is >48 hours, or if the duration is unknown, then an oral anticoagulant agent (warfarin, dabigatran, factor Xa inhibitor) should be given for 3 weeks before cardioversion at doses providing an INR between 2 and 3 if using warfarin.[6] Studies in patients with AF showed that those who were anticoagulated with warfarin before cardioversion had a lower incidence (0.8%) of emboli than those who were not anticoagulated (5.3%).[26] Alternatively, a TEE can be used to determine whether atrial clots have formed.[6,27] Atrial clots form most often in a small side pouch on the atria called the atrial appendage.[28] Because the frequency of right atrial appendage thrombosis is half that of left atrial appendage thrombosis in patients with AF, the risk of stroke is enhanced much more than the risk of pulmonary embolism.[28]

If no clot is observed on TEE, then there is a low risk for stroke with cardioversion of AF.[27] However, if an atrial clot is evident on TEE, J.K. would need to be adequately anticoagulated for 3 weeks before cardioversion to prevent embolization of the clot and stroke. If cardioversion is successful, patients should remain on an oral anticoagulant agent for at least 4 weeks after cardioversion because normal atrial contraction may not return for up to 3 weeks, and patients may be at risk of late embolization.[29] The decision to provide long-term oral anticoagulation is dependent on the patient's

underlying stroke and bleeding risk. This will be discussed further below.

Conversion—Chemical with Ibutilide, Propafenone, Flecainide

Case 15-1, Question 9: J.K. was found to be free of atrial clots. Chemical cardioversion with ibutilide is planned for tomorrow. If J.K. fails to convert with ibutilide, he will be electrically cardioverted later in the day. How does ibutilide therapy compare with the other therapeutic choices for chemical cardioversion?

The most effective method of cardioversion is by direct current (DC) cardioversion (see Electrical Cardioversion section). However, the use of DC cardioversion may be undesirable if the patient is a poor candidate for conscious sedation or if the patient is not willing to undergo DC cardioversion. In these situations, pharmacologic cardioversion may be attempted. Many class I and III antiarrhythmic agents have been evaluated for efficacy in placebo-controlled trials for conversion of AF or atrial flutter to normal sinus rhythm. The available agents with the most positive data for chemical conversion include IV ibutilide, oral propafenone, oral flecainide, oral and IV amiodarone, and oral dofetilide. This section will focus on ibutilide, propafenone, and flecainide.

IV ibutilide, a class III antiarrhythmic agent with potassium channel blocking and slow sodium channel enhancing effects, was the first agent that the U.S. Food and Drug Administration (FDA) approved for the termination of recent-onset AF and atrial flutter.[30] Ibutilide is administered as a 1-mg infusion for 10 minutes, followed by another 1-mg infusion for 10 minutes if the conversion has not occurred by 10 minutes after the first infusion. The conversion rate for recent-onset AF is 35% to 50%; the conversion rate is 65% to 80% in atrial flutter. In a retrospective study of hospital inpatients with either AF or atrial flutter, 50% of patients converted initially (41% conversion AF, 65% atrial flutter), but only 33% of patients left the hospital in sinus rhythm. If the duration of AF or atrial flutter before cardioversion was <15 days, significantly more patients remained in sinus rhythm at

discharge compared with patients who had AF or atrial flutter for more than 15 days before cardioversion.[30] As is the case with most class III antiarrhythmic agents, the main adverse effect is TdP, which occurred in ~4% of patients. Ibutilide should be avoided in patients with hypokalemia, hypomagnesemia, QT prolongation, and a low ejection fraction (<30%). Aside from the risk of TdP, therapy is well tolerated.[31–33]

Propafenone is a class Ic agent with β-blocking properties. When given in doses of 450 to 750 mg orally (600 mg was the most common dose), the initial conversion rate in patients with AF ranged from 41% to 57%. In contrast to ibutilide, no patients experienced ventricular arrhythmias (including TdP), but a risk of hypotension, bradycardia, and QRS prolongation was noted.[34–36]

Oral flecainide is another class Ic antiarrhythmic agent. In one study, 300 mg of oral flecainide converted 68% of patients to sinus rhythm within 3 hours and 91% of patients by 8 hours. The efficacy in atrial flutter has yet to be established. Sinus node dysfunction, prolongation of intraventricular conduction, dizziness, weakness, and gastrointestinal (GI) disturbances have been reported.[37,38]

A β-blocker or nondihydropyridine calcium channel antagonist should be administered ≥30 minutes before administering the Vaughan Williams class Ic agent to prevent a rapid ventricular response owing to 1:1 AV conduction during atrial flutter.[7] J.K. is not a candidate for these agents owing to his structural heart disease.

Electrical Conversion

Case 15-1, Question 10: J.K. received two doses of IV ibutilide. After the second dose, he converted to normal sinus rhythm for only 5 minutes, then returned to AF. J.K. is scheduled for electrical cardioversion in 6 hours. What is electrical cardioversion? How efficacious and safe is it?

DC cardioversion quickly and effectively restores 85% to 90% of patients with AF to normal sinus rhythm.[29] If DC conversion alone is ineffective, it can be repeated in combination with antiarrhythmic

drugs.[6,39] In one study, the success rate of electrical cardioversion was significantly higher in AF patients (duration of AF averaged 119 days) with ibutilide pretreatment (1 mg) compared with those without pretreatment (100% vs 72%; *P* = .001).[39] This is because ibutilide pretreatment lowered the energy requirement for atrial defibrillation by 27% (*P* = .001). TdP occurred in 3% of patients receiving ibutilide, all of whom had an ejection fraction <20%. Flecainide, propafenone, amiodarone, and dofetilide could also be considered for enhancing DC cardioversion.[6]

DC cardioversion is clearly indicated for patients who are hemodynamically unstable. A reason one may wish to avoid DC conversion is that anesthesia (short-acting benzodiazepine, barbiturate, or propofol) is required for the procedure.

Maintenance of Sinus Rhythm

Case 15-1, Question 11: J.K. is discharged after successful DC conversion. However, when he returns for a follow-up visit 2 weeks later, he is found to be in AF again. He again reports frequent palpitations. His physician would like to initiate an antiarrhythmic drug to maintain normal sinus rhythm. Which agent(s) would be the best option for this patient?

To choose the best antiarrhythmic agent for J.K., the efficacy and adverse effect profiles for each agent should be reviewed. Class Ia, Ic, and III antiarrhythmic drugs (see Tables 15-2 and 15-3) prevent the recurrence of AF. Flecainide, sotalol, dofetilide, and dronedarone are approved by the FDA for the maintenance of sinus rhythm. Propafenone and amiodarone are commonly used but Ia agents are not.

Flecainide and Propafenone

The class Ic agents flecainide and propafenone are effective in suppressing AF.[40–44] The efficacy rate may be as high as 61% to 92% for flecainide.[45,46] Flecainide and possibly other class Ic agents are proarrhythmic, especially in patients with structural heart

disease, and they should be avoided in such patients. Propafenone, a class Ic agent with β-blocking properties, is as efficacious as flecainide and is relatively safe in patients without ischemic heart disease and an ejection fraction >35%; it may be preferred in patients who require additional AV blockade to control ventricular response. In a direct comparison with flecainide (200–300 mg/day), propafenone (450–900 mg/day) was equally safe and effective. Over the course of 12 months, a similar percentage of patients (~12% in each group) did not have adequate control of their arrhythmia. Adverse events were comparable and occurred in 10.3% of patients on flecainide and 7.7% of patients on propafenone. Of all the adverse events noted, only one patient who was receiving propafenone developed a ventricular arrhythmia. Another 1-year comparative study of propafenone versus flecainide demonstrated similar efficacy, but this study showed a trend toward better tolerability in the flecainide group.[47,48]

Class III Agents

Case 15-1, Question 12: J.K. is to begin dofetilide today. He is admitted to the hospital for dofetilide initiation. Why would J.K. need to be admitted for dofetilide initiation? Is it necessary to initiate all antiarrhythmic medications in the hospital?

Class III agents (sotalol, dofetilide, amiodarone, and dronedarone) prolong refractoriness in the atria, ventricles, AV node, and accessory pathway tissue and can prevent recurrence of AF. All of these agents act by blocking potassium channels; however, sotalol also has additional β-blocking properties.[49–51] Both amiodarone and dronedarone block sodium channels and calcium channels and have antiadrenergic effects in addition to potassium channel blocking properties.[49,51]

Sotalol, Amiodarone, Dofetilide, and Dronedarone

The efficacy of sotalol in delaying the recurrence of AF was evaluated in a double-blind, placebo-controlled, multicenter, randomized trial that enrolled 253 patients with AF or atrial flutter.[52] The median times to recurrence were 27, 106, 229, and 175 days with placebo, sotalol 160 mg/day (divided into two doses), sotalol 240 mg/day (divided into two doses), and sotalol 320 mg/day (divided into two doses), respectively. Sotalol is contraindicated in patients with a creatinine clearance (CrCl) <40 mL/minute because the drug is largely renally cleared and can cause TdP in high concentrations. In a comparative study versus propafenone, sotalol was similarly effective in producing ≥75% reduction in AF recurrence (79% of patients on propafenone vs 76% on sotalol). Bradycardia, dizziness, and GI disturbances were the most common intolerable side effects.[53] Sotalol should not be used in patients with HFrEF owing to the negative inotropic effects of the drug. It may be useful as a first-line agent in patients with AF and concomitant underlying coronary artery disease or in patients with no cardiovascular disease.[6]

Amiodarone is more effective at maintaining sinus rhythm than sotalol and propafenone.[54] The Canadian Trial of Atrial Fibrillation (CTAF) compared the ability of low-dose amiodarone (200 mg/day) versus propafenone (450–600 mg/day) and sotalol (160–320 mg/day) to prevent recurrence of AF.[54] After a mean follow-up of 16 months, 35% of the amiodarone-treated patients had a recurrence of AF versus 63% in the combined group with sotalol and propafenone (P = .001). Because of its unusual pharmacokinetics and potential serious adverse effects (see **Table 15-3** and Case 15-7, Question 2), amiodarone is only recommended as a first-line choice for patients with HF, for which it has specific safety data, or for patients with significant left ventricular hypertrophy.[6] Amiodarone could also be used when other agents such as sotalol, propafenone, or dofetilide have failed.[6,55]

Dofetilide is an effective pharmacologic agent for conversion to, and maintenance of, normal sinus rhythm. Two clinical trials, EMERALD (European and Australian Multicenter Evaluative Research on Atrial Fibrillation Dofetilide)[56] and SAFIRE-D

(Symptomatic Atrial Fibrillation Investigation and Randomized Evaluation of Dofetilide),[57] have shown conversion rates of 30% in patients with AF or atrial flutter receiving higher doses of dofetilide. Patients failing chemical conversion received electrical conversion. If this conversion succeeded, they were continued on dofetilide for 1 year. At 1 year, 60% of those converted were still in sinus rhythm with the 500-µg dose. Also, dofetilide appears to exert neutral effects on mortality rates in HF and post-MI patients.[58,59]

Dofetilide dose is based on the patient's CrCl; the doses are 500, 250, and 125 µg twice daily with CrCl >60, 40 to 60, and 20 to 39 mL/minute, respectively. Drug interactions pose a significant problem with dofetilide. Cimetidine, ketoconazole, prochlorperazine, megestrol, and trimethoprim (including in combination with sulfamethoxazole) inhibit active tubular secretion of dofetilide and can elevate dofetilide plasma concentrations.[49,60] Because the incidence of TdP is directly related to dofetilide plasma concentrations, concomitant use with these agents is contraindicated. Concomitant administration of dofetilide with verapamil or hydrochlorothiazide increases the incidence of TdP by an unclear mechanism and is contraindicated as well. Concurrent use of agents that can prolong the QTc interval is not recommended with dofetilide. Dofetilide also undergoes metabolism by the cytochrome P-450 CYP3A4 isoenzyme to a minor extent. Therefore, inhibitors of this isoenzyme (eg, azole antifungal agents, protease inhibitors, serotonin reuptake inhibitors, amiodarone, diltiazem, nefazodone, zafirlukast) should be coadministered with caution with dofetilide. Other agents that can potentially increase dofetilide levels (through inhibition of tubular secretion) include metformin, triamterene, and amiloride. Hence, these agents should be cautiously coadministered with dofetilide.[49,60]

Dofetilide is considered a first-line agent for patients with HFrEF or coronary artery disease, as the impact on mortality in this patient population is neutral.[6] Dofetilide can also be considered as a first-line agent for patients without cardiovascular disease but should be avoided in patients with severe left ventricular hypertrophy.[6]

Dronedarone is structurally and pharmacologically similar to amiodarone; however, it lacks iodine, and it has a much smaller volume of distribution than amiodarone. The lack of iodine may make dronedarone less likely to cause thyroid-related or other adverse effects.[51] Dronedarone has been shown to have modest efficacy in maintaining sinus rhythm when compared with placebo. The rate of recurrence of AF at 1 year is ~40%, and the number of days to recurrence is nearly doubled with dronedarone.[61] The major clinical trial evaluating dronedarone was the A PlaceboControlled, Double-Blind, Assess the Efficacy of Dronedarone for the Prevention of Cardiovascular Hospitalization or Death from any Cause in Patients with Atrial Fibrillation/Atrial Flutter (ATHENA) study. The primary end point of ATHENA was a composite of death or cardiovascular hospitalization, and patients received either dronedarone 400 mg twice daily or placebo for at least 1 year.[62] The primary composite end point was significantly reduced from 39.4% with placebo to 31.9% with dronedarone. This reduction in the composite was completely attributable to the reduction in cardiovascular hospitalizations, most of which were related to AF recurrence. GI events were the most common type of adverse effect with dronedarone in this study. It should be noted that patients with recent decompensated HF or New York Heart Association (NYHA) class IV HFrEF were excluded from this trial. The exclusion of patients with severe or unstable HF was related to negative findings that led to the early discontinuation of the ANDROMEDA study.[63] ANDROMEDA was designed as a safety study to evaluate the impact of dronedarone on mortality in patients with HF. Patients admitted with NYHA class III or IV HFrEF were included in this study. The study was stopped early because of an approximate doubling in the risk of death with dronedarone as compared with placebo. Therefore, dronedarone is contraindicated in a patient with severe or recently decompensated HF. Based on the findings of the PALLAS study, dronedarone should be avoided in patients with permanent AF as well.[64] This study found that the rate of stroke, HF, and cardiovascular death was increased when dronedarone was used in this patient population. Dronedarone has also been compared

directly with amiodarone.[65] In this study, dronedarone was less effective than amiodarone but was less likely than amiodarone to cause thyroid, neurologic, skin, or ocular adverse effects. GI adverse effects were more common with dronedarone.[65] Dronedarone is appropriate as a first-line agent for patients with AF and concomitant coronary artery disease, and possibly left ventricular hypertrophy or in patients with no cardiovascular disease. Dronedarone should not be used in a patient with severe HF symptoms or a recent hospitalization for HF but may be used with mild, well-controlled HF.[6]

In view of J.K.'s HF, sotalol, propafenone, and flecainide would not be indicated. Although dronedarone may be better tolerated than amiodarone, it would be contraindicated because J.K. was recently admitted with decompensated HF. Therefore, the only available options for J.K. would be either dofetilide or amiodarone, both of which have proven safe in patients with HF. Selection between dofetilide and amiodarone could be based on renal function, the presence of any major drug interactions, or the desire to avoid adverse effects with amiodarone.

Dofetilide was approved with the requirement for in-hospital initiation because of the relatively high risk of TdP in clinical trials. ECG monitoring is required for patients being initiated on dofetilide for a minimum of 3 days in a properly equipped facility. The initial regimen is determined by the patient's estimated CrCl. The QTc interval must be measured (using a 12-lead ECG) 2 to 3 hours after the first dose and each subsequent dose while the patient is hospitalized. If the QTc interval increases by >15% or if it surpasses 500 milliseconds (>550 milliseconds in patients with ventricular conduction abnormalities) after the first dose, the dofetilide regimen should be reduced by 50%. If the QTc interval exceeds the above parameters any time after the second subsequent dose, dofetilide should be discontinued.

Sotalol may also be arrhythmogenic in high doses, and the risk of inducing TdP has prompted its manufacturer to mandate a minimum of 3 days of ECG monitoring in a properly equipped facility during therapy initiation as well. Further, during initiation and titration, QTc intervals should be monitored 2 to 4 hours after each dose. In fact,

most antiarrhythmic agents for AF should probably be initiated in the inpatient setting, except amiodarone owing to the low risk of proarrhythmia with this drug.[6]

STROKE PREVENTION

Antithrombotic therapy

Case 15-1, Question 13: J.K. is discharged from the hospital on dofetilide 500 µg twice daily, which is appropriate given his CrCl of 92 mL/minute. He has been doing fine for 2 weeks after discharge. Should J.K. remain on warfarin therapy? Could any other antithrombotic options be considered?

Patients with nonvalvular and valvular AF have a 5- and 17-fold increased risk for stroke compared with patients without AF, respectively.[3,4] Stroke can lead to death or significant neurologic disability in up to 71% of patients, with an annual recurrence rate as high as 10%.[66]

In three large, randomized trials, patients with nonvalvular AF benefited from antithrombotic therapy.[66–70] In the Stroke Prevention in Atrial Fibrillation (SPAF) study, both aspirin 325 mg/day and warfarin (titrated to an INR of 2.0–4.5) reduced the risk of stroke significantly with an acceptable level of hemorrhagic complications.[69] The results of SPAF II, a direct comparison of warfarin and aspirin, indicated that warfarin was more effective than aspirin in preventing stroke.[70] These results were verified by the Copenhagen Atrial Fibrillation, ASpirin, AntiKoagulation (AFASAK) study, which found warfarin to be significantly better than aspirin and placebo at preventing cerebral emboli and overall vascular deaths (cerebral and cardiovascular).[67] An oral direct thrombin antagonist (dabigatran) and oral factor Xa antagonists (rivaroxaban, apixaban, and edoxaban) are now available for stroke prevention in AF. These newer anticoagulant agents have been shown to have similar or better efficacy and safety for AF stroke prevention compared to warfarin.[71–73]

Dabigatran is approved by the FDA to reduce the risk of stroke and systemic embolism in patients with nonvalvular AF.[74] In the Re-

Ly trial, dabigatran 110 mg twice daily and 150 mg twice daily was compared with warfarin in patients with a $CHADS_2$ score of 1 or more (average $CHADS_2$ score of 2.1). The $CHADS_2$ score is a tool used to estimate stroke risk and was used prior to the CHA_2DS_2-VASc score. In this study, the lower dose of dabigatran was noninferior to warfarin for stroke prevention but was associated with less bleeding. High-dose dabigatran was superior to warfarin for stroke prevention but comparable in bleeding.[75] The most common nonbleeding adverse event in this study was GI upset. It should also be noted that dabigatran capsules should not be chewed or opened.

The three oral factor Xa inhibitors that are currently approved for the prevention of stroke and systemic embolus in patients with AF include rivaroxaban, apixaban, and edoxaban. Each of these agents has been compared directly to warfarin using fairly similar study designs.[71–73] Rivaroxaban and edoxaban were found to be noninferior to warfarin in stroke/systemic embolus prevention, whereas apixaban was found to be superior to warfarin in efficacy. Major bleeding occurred less frequently with edoxaban and apixaban and at a similar rate with rivaroxaban compared to warfarin. Although efficacy and safety of all the new agents differed when compared with warfarin, there are no direct comparisons between any of the newer antithrombotic options. As such, no firm conclusions can be drawn regarding the optimal agent to choose. However, in a patient who is perceived to have a high bleeding risk, it is reasonable to select apixaban or edoxaban, given the bleeding risk advantage of these agents relative to warfarin.[72,73]

Some differences between the newer agents could be considered when selecting an anticoagulant regimen for a patient. For example, each agent has different recommendations for use with kidney dysfunction. None of the newer oral agents should be used in patients with a CrCl <15 mL/minute. The “renal doses” of rivaroxaban (15 mg/day with CrCl of 15–49 mL/minute) and edoxaban (30 mg/day with CrCl of 15–50 mL/minute) were evaluated in the ROCKET AF and ENGAGE AF TIMI 48 studies, whereas the renal dose adjustment recommended for dabigatran (75-mg twice-

daily dose for those with a CrCl of 15–30 mL/minute) was based on extrapolated pharmacokinetic data.[71,73,76] Apixaban does not require dosage adjustment specifically based on a CrCl, but adjustment should occur if the patient has two or more high-risk characteristics (body weight 132.27 pounds [<60 kg], serum creatinine >1.5 mg/dL, or age >80 years). In addition, apixaban product information suggests that this reduced dose produces drug concentrations in patients with end-stage renal disease (ESRD) on intermittent hemodialysis, comparable to the normal dose used for those without renal dysfunction in clinical trials. This suggestion is based on pharmacokinetic data, and it is unclear whether patients with ESRD derive the same efficacy and safety with the reduced dose. Interestingly, edoxaban is less effective and should not be used when CrCl is >95 mL/minute. Therefore, edoxaban, apixaban, or rivaroxaban may be a more evidence-based option than dabigatran for a patient with poor kidney function, and edoxaban would be an inappropriate choice for the patient with very good kidney function.[71–74]

The drug interaction profiles of the oral direct thrombin inhibitor or oral factor Xa inhibitors are favorable compared to that of warfarin. All of the newer anticoagulant options interact with rifampin. Rivaroxaban and apixaban also interact with other strong inhibitors and inducers of both the P-glycoprotein and CYP 3A4 systems. Dabigatran interacts with inhibitors of P-glycoprotein (ketoconazole and dronedarone); however, no change in therapy is required unless the interacting drugs are used in a patient who also has a CrCl <50 mL/minute. At this time, no notable interactions have been identified with edoxaban other than the interaction with rifampin. Although the number of interactions with the newer anticoagulants is fewer than with warfarin, it will still be important to evaluate for the presence of interactions at therapy initiation and when the drug therapy regimen is changed. An advantage of dabigatran and the oral factor Xa antagonists is that these agents do not require frequent monitoring and dosage adjustment to assure an appropriate level of anticoagulation. A potential disadvantage is that it is often not possible to monitor the extent of anticoagulation in the setting of

bleeding or when an urgent procedure or surgery is needed. In the last few years, strategies for the reversal of these agents have become available. Dabigatran can be reversed by idarucizumab, a monoclonal antibody that binds to dabigatran, rendering the anticoagulant inactive.[77] The factor Xa antagonists, rivaroxaban and apixaban, can be reversed with andexanet alfa. Andexanet alfa is a recombinant inactive factor Xa molecule that binds to the Xa antagonist, preventing anticoagulation.[78] Data do not exist to support the use of andexanet alfa for other factor Xa antagonists (edoxaban, betrixaban). Therefore, the best available evidence suggests that concentrated blood factor products (four-factor prothrombin complex concentrates and Factor Eight Inhibitor Bypassing Activity (FEIBA)) may be options for reversing the effects of these agents.[78]

Male patients with a CHA_2DS_2-VASc score of ≥2 and female patients with a CHA_2DS_2-VASc of ≥3 should receive anticoagulant therapy for stroke prophylaxis.[18] Warfarin (INR target 2–3), dabigatran, rivaroxaban, apixaban, and edoxaban are all recommended as antithrombotic agents for stroke prophylaxis.[18] Dabigatran, rivaroxaban, apixaban, and edoxaban are preferred over warfarin, except in the setting of moderate-to-severe mitral stenosis or mechanical heart valve. If CHA_2DS_2-VASc is 1 in males and 2 in females and the patient does not have moderate-to-severe mitral stenosis or a mechanical valve, anticoagulant stroke prophylaxis could be considered but is not absolutely necessary. If a patient's INR is difficult to control on warfarin, a direct thrombin inhibitor or oral Xa antagonist could be used.[7] It should be noted that patients with AF and valvular disease should only be treated with warfarin for stroke prophylaxis as data with valvular AF are either unfavorable or unavailable with the newer agents in this patient population.[18]

Even though J.K. is in normal sinus rhythm at this time, in the AFFIRM trial, only 73% and 63% of patients randomized to rhythm control remained in sinus rhythm at 3 and 5 years, respectively.[19] As such, the use of an antiarrhythmic drug does not eliminate the risk of stroke, and in fact, patients may return to AF and not be aware they are no longer in normal sinus rhythm. J.K. has a CHA_2DS_2-VASc

score of 4 and does not appear to have any factors that would suggest a high bleeding risk (no recent history of GI bleeding, etc). Therefore, he should continue to receive anticoagulation for stroke prophylaxis.[18] Although J.K. is currently taking warfarin, he could be changed to any of the other available anticoagulants if after he learns about the other options, he feels it would align with his preferences and/or lifestyle.

CASE 15-2

QUESTION 1: M.P. is a 38-year-old female who has had frequent episodes of atrial flutter for the past 2 years. She has no other medical history and is taking metoprolol 50 mg twice daily. She does not want to take the drug any longer because it reduces her exercise tolerance.

Does the treatment of atrial flutter differ from the treatment of AF, and what is the role of radiofrequency catheter ablation for M.P.?

Atrial flutter is an arrhythmia that often reverts to sinus rhythm or progresses to AF. If atrial flutter is episodic, its underlying cause should be identified and treated if possible. If a patient remains in atrial flutter, the treatment goals (control of ventricular rate, return to normal sinus rhythm) are the same as those for AF. Similar agents and doses can be used to control the ventricular response. Chemical conversion, low-energy (<50 J) DC cardioversion, or rapid atrial pacing may acutely convert atrial flutter back to sinus rhythm, but the recurrence of atrial flutter is high.

Radiofrequency catheter ablation therapy could be used as a nonpharmacologic treatment for atrial flutter and AF.[6] With both atrial flutter and AF, an EP study is performed to identify whether ablation can be performed. Various sections of the atria and pulmonary veins (where they intersect with the atria) are probed with a catheter that delivers cardiac pacing. If an area is stimulated with pacing and an atrial ectopic or reentrant focus is recognized, that area could be ablated. Ablation destroys the tissue that is integral either to the initiation or to the maintenance of the arrhythmia by delivering electrical energy through electrodes on the catheter. If the focus of the arrhythmia is in the atrial tissue (typically for atrial flutter), then

the focus itself is ablated. This procedure is successful in 75% to 90% of cases and can be recommended for patients with atrial flutter who are drug-resistant or drug-intolerant or do not desire long-term therapy. In AF, an ectopic focus originating in the pulmonary veins can often initiate arrhythmia. In this case, circumferential ablation, in which a circle of ablated tissue is made around the pulmonary veins, is performed. Circumferential ablation does not prevent the ectopic impulses from the pulmonary veins from occurring; however, it does prevent the propagation of the impulse into the atria and may reduce the recurrence of AF. Recent data comparing ablation to antiarrhythmic drug therapy in patients with PAF suggest that ablation is more effective in preventing recurrence of AF than medications.[6,78]

Radiofrequency ablation therapy may be suitable for M.P. However, if exercise intolerance is her primary issue, this might be relieved by switching M.P. to another drug such as verapamil.

Paroxysmal Supraventricular Tachycardia

CLINICAL PRESENTATION

CASE 15-3

Question 1: B.J., a 32-year-old female, presents to the emergency department (ED) with symptoms of fatigue and palpitations. She has had similar episodes ~twice a year for the past 2 years but has not sought medical attention for them. She is in no apparent distress and has a temperature of 98.0 °F (36.66 °C), heart rate of 185 beats/minute, BP of 95/60 mm Hg, and respiratory rate of 12 breaths/minute. Her ECG (**Fig. 15-5**) shows regular rhythm with a heart rate of 185 beats/minute. The P waves cannot be found, and the QRS complex is 110 milliseconds (normal, <120 milliseconds). She has no past medical history of note.

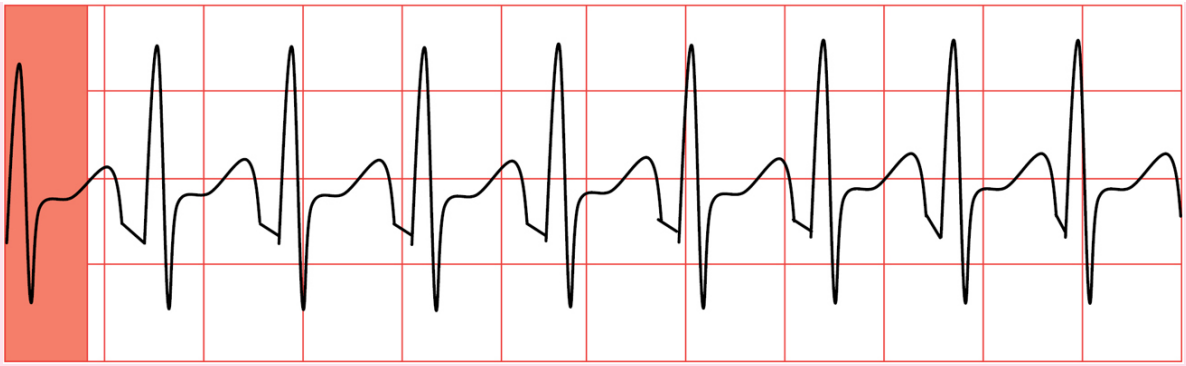

Figure 15-5 Supraventricular tachycardia. Note the lack of P waves, narrow QRS complexes, and rapid rate.

What is the clinical presentation of PSVT, and what are the consequences of this arrhythmia?

PSVT often has a sudden onset and termination. At the time of PSVT, the heart rate is usually 180 to 200 beats/minute. As illustrated by B.J., patients experience palpitations and often nervousness and anxiety. In patients with a rapid ventricular rate, dizziness and syncope can occur, and the rhythm may degenerate to other serious arrhythmias. Angina, HF, or shock may be precipitated by underlying severe atherosclerosis or left ventricular dysfunction, but this is not part of B.J.'s past medical history. There is no evidence that patients with episodes of PSVT are at an increased risk of stroke.

ARRHYTHMOGENESIS AND REENTRY

Case 15-3, Question 2: What is the arrhythmogenic mechanism of PSVT?

AV nodal reentry is the most common mechanism of paroxysmal supraventricular arrhythmias (see Fig. 15-2). Here AV nodal impulses are blocked in one of two directions in an antegrade fashion but when reaching the end, conducts in a retrograde fashion setting up a circular reentrant circuit. Reciprocating tachycardias occur when there is an accessory pathway for conduction of

impulses between the atria and ventricles, like with WPW syndrome, and PSVT results (**Fig. 15-6**).

D, Normal impulse conduction through the AV node, but abnormal retrograde conduction up an accessory pathway, as would be seen in a patient with Wolff–Parkinson–White syndrome.

TREATMENT

Nondrug treatment

Valsalva Maneuver

CASE 15-3, QUESTION 3: B.J. tries the Valsalva maneuver, and her ventricular rate is reduced to 150 beats/minute; the other parameters are unchanged. She is given IV adenosine 6 mg, administered over 1 minute, with no effect on the PSVT rate. Another dose of adenosine 12 mg given over 1 minute has no effect. No side effects are noted from therapy. What treatment options can be used if B.J. is hemodynamically unstable? What is the Valsalva maneuver? What is the probable reason for B.J.'s unresponsiveness to adenosine? Are there any drug interactions that might diminish adenosine's effect?

Although her BP is low at 95/60 mm Hg, B.J. is maintaining an adequate perfusion pressure, so vagal maneuvers should be attempted first. Two common vagal techniques are pressure over the bifurcation of the internal and external carotid arteries and the Valsalva maneuver (forcible exhalation against a closed glottis, similar to bearing down to have a bowel movement). The increase in pressure induced by these maneuvers is sensed by the baroreceptors, causing a reflex decrease in sympathetic tone and an increase in vagal tone. The increase in vagal tone will terminate in 10% to 30% of cases.[79] If B.J. was hemodynamically unstable or becomes hemodynamically unstable, she should receive synchronized DC cardioversion.

Drug therapy

Adenosine

Because most PSVT episodes involve reentry in the AV node, drugs that block the AV node (negative dromotropic drugs) are generally effective. Adenosine, a purine nucleoside that exerts a transient negative chronotropic and dromotropic effect on cardiac pacemaker tissue,[80] is considered the drug of choice for the acute treatment of PSVT because of its rapid and brief effect. An initial 6-mg IV bolus is given; if this is unsuccessful within 2 minutes, it can be followed by one or two 12-mg IV boluses, up to a maximum of 30 mg. Because of its short half-life (9 seconds), adenosine should be administered as a rapid bolus (over 1–3 seconds), followed immediately by a saline flush. Adenosine begins to be metabolized immediately after entering the bloodstream; therefore, B.J.'s failure to respond is likely attributed to the prolonged (1 minute) infusion time.

Theoretically, adenosine may be ineffective or higher doses may be required in patients who are receiving theophylline because theophylline is an effective adenosine receptor blocker. Larger doses of other methylxanthines (caffeine, guarana) may also theoretically interact like theophylline. Conversely, concomitant use of dipyridamole may accentuate adenosine's effects because dipyridamole blocks the adenosine uptake (and subsequent clearance).[80]

Case 15-3, Question 4: B.J. is given 12 mg of adenosine IV for 2 seconds, followed by a 20-mL normal saline flush. Thirty seconds later, she experiences chest tightness and pressure. What is the explanation for these symptoms?

B.J. is experiencing a common side effect of adenosine. Patients receiving adenosine should be warned that they may feel transient chest heaviness, flushing, or a feeling of anxiety. Shortness of breath and wheezing may be observed in patients with asthma. The denervated heart of the patient who has undergone heart transplant is particularly sensitive to adenosine; therefore, lower doses of adenosine should be used.

Calcium Channel Blockers

Case 15-3, Question 5: B.J. is still in PSVT. What other acute therapeutic options should be considered at this time?

Nondihydropyridine calcium channel blockers, verapamil, and diltiazem can be used in patients with PSVT. Verapamil (5–10 mg or 0.075–0.15 mg/kg IV given over 2 minutes) achieves peak therapeutic effects in 3 to 5 minutes after dosing and can be repeated at 10- to 15-minute intervals to a maximal dose of 20 mg if needed. The elderly should receive the verapamil infusion over 3 minutes to minimize the risk of adverse events. Diltiazem is given as a 0.25-mg/kg IV bolus over 2 minutes, and a second bolus of 0.35 mg/kg can be given 15 minutes later if the effect is inadequate. Both of these calcium channel blockers have an 85% conversion rate.[80] However, verapamil should not be used in patients with wide complex tachycardia of unknown origin because it may lead to hemodynamic compromise and potentially VF. β-Blockers and digoxin can be used if calcium channel blockers and adenosine fail.

Case 15-3, Question 6: B.J. is given 5-mg IV verapamil, followed by an additional 5 mg 10 minutes later. She converts to normal sinus rhythm 3 minutes after the second dose. Because she has experienced symptoms that could be attributed to PSVT in the past, she may be a candidate for chronic therapy to slow conduction and increase refractoriness at the AV node. Which agents have been evaluated for this indication? Is there a role for radiofrequency catheter ablation therapy for PSVT?

Radiofrequency catheter ablation is frequently used as a definitive treatment for PSVT. EP testing is used to determine the location of the reentrant tract, which then can be ablated, thereby interrupting accessory pathways and reentrant circuits. This treatment approach is potentially curative and is performed by an electrophysiologist. Patients who are not candidates for ablation, or who do not wish to undergo the procedure, can receive medications on a chronic basis. PSVT is managed with agents that slow conduction and increase

refractoriness in the AV node, thereby preventing a rapid ventricular response. These include oral verapamil, diltiazem, β-blockers, or digoxin. Class Ic and III agents are used occasionally to slow conduction and increase refractoriness of the fast bypass tract to prevent triggering impulses such as premature atrial and ventricular contractions.

B.J. has had a few episodes of PSVT in the past and may be a candidate for curative therapy with ablation. Alternatively, because she responded to IV verapamil, if she did not want to undergo ablation, oral sustained-release (SR) verapamil could be prescribed at a dosage of 240 mg/day.

Wolff–Parkinson–White Syndrome

CASE 15-4

Question 1: M.B., a 35-year-old male, presents to the ED with a chest palpitations for 4 hours with an intermittent feeling of almost passing out (presyncope). M.B.'s vital signs are BP, 96/68 mm Hg; pulse, 226 beats/minute, irregular; respiratory rate, 15 breaths/minute; and temperature, 98.7 °F (37.06 °C). A rhythm strip confirms AF, with a QRS width varying from 0.08 to 0.14 seconds. To control the ventricular rate, 10 mg of IV verapamil is administered over 2 minutes. Within 2 minutes of completing the infusion, VF is noted on the monitor. M.B. is defibrillated, and normal sinus rhythm is restored. A subsequent ECG demonstrates a P-R interval of 100 milliseconds (normal, 120–200 milliseconds) and delta waves, compatible with WPW. He relates a past medical history of many similar self-terminating episodes since he was a teenager but he has no atherosclerotic heart disease or HF. He took an unknown medication 5 years ago that decreased the occurrence of the palpitations, but he stopped taking it because of side effects.

What is WPW syndrome?

WPW is a preexcitation syndrome in which there is an accessory bypass tract connecting the atria to the ventricles (Fig. 15-6). An impulse can travel down this pathway and excite the ventricle before the expected regular impulse through the AV node arrives. If there is antegrade conduction over the bypass tract while the patient is in normal sinus rhythm, the ECG will demonstrate a short P-R interval

(<100 milliseconds), a delta wave that represents a fused complex from preexcitation, and the regular QRS complex after AV conduction. PSVT and AF occur in these patients at a higher incidence than in the general population of the same age.[81–83] Similar to M.B., the rapid heart rate experienced during the tachycardia may cause palpitations, light-headedness, and fatigue. When patients with WPW develop AF, there is a danger that the rapid atrial impulses will be conducted directly to the ventricle through the bypass tract, causing a rapid ventricular rate that may evolve into VF. Verapamil (like diltiazem, β-blockers, adenosine, and amiodarone) can increase this risk by increasing the effective refractory period of the AV node and indirectly reducing the effective refractory period in the bypass tract.[83]

Case 15-4, Question 2: Why did verapamil cause VF in M.B.? What therapies would be appropriate for M.B., and what drugs should be avoided?

Because M.B. had AF, the rapid atrial impulses were conducted directly down the bypass tract to the ventricle, causing VF.

The antiarrhythmic drugs used to chemically convert patients with AF who have WPW, such as M.B., include procainamide, propafenone, flecainide, and dofetilide. DC cardioversion is an option for more emergent conversion of AF in patients with WPW and hemodynamic instability. Radiofrequency ablation of the bypass tract is curative for many patients with WPW and is indicated for people who maintain preexcitation during exercise stress testing, a shortest preexcited RR interval <250 milliseconds, symptoms like syncope of palpitations, or preexisting structural heart disease. M.B. has symptoms associated with AF in WPW and should undergo evaluation from a cardiologist to determine if ablation is appropriate at this time.[81–83]

Further therapy for M.B. may not be useful at this time. However, if he has recurrent AF or other symptomatology associated with WPW, radiofrequency catheter ablation could be indicated.

CONDUCTION BLOCKS

Various arrhythmias can result from blockage of impulse conduction. These can occur above the ventricle, such as first-, second-, and third-degree (complete) AV blocks. Others, such as right or left bundle branch block (RBBB or LBBB) and trifascicular block, originate below the bifurcation of the His bundle.[84]

CASE 15-5

QUESTION 1: H.T., a 63-year-old male with a history of MI treated with metoprolol tartrate 75 mg twice daily, was admitted to the hospital 12 hours ago with a low pulse rate of 50 beats/minute, BP of 89/57 mm Hg, severe dizziness, and low exercise tolerance. On admission, the rhythm strip is shown in **Figure 15-7** (Wenckebach or type I second-degree AV block).

How is second-degree AV block different from first- or third-degree AV block? Which one is the most severe?

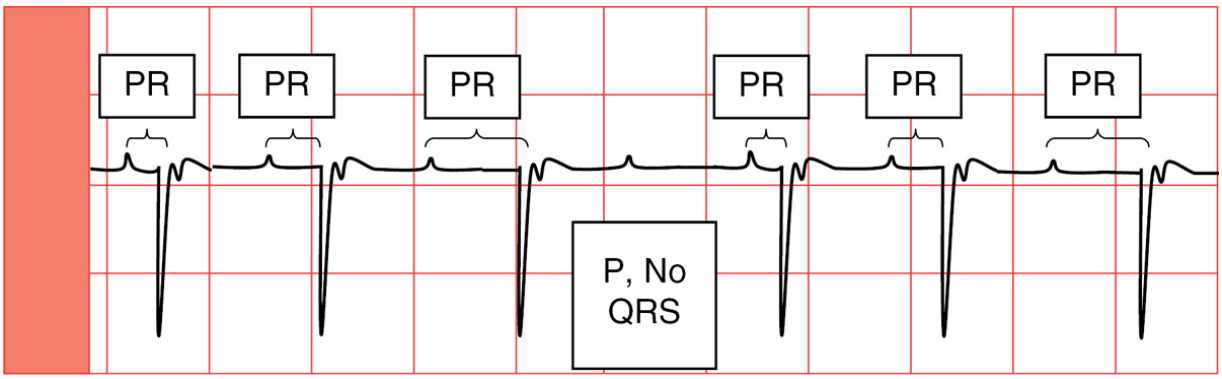

Figure 15-7 Second-degree atrioventricular block type I. The P–R interval progressively prolongs until a QRS complex is not conducted and then the cycle repeats.

First-degree AV block usually is asymptomatic. The ECG will show P waves with a prolonged P-R interval (normal, <200 milliseconds), but each P wave is followed by a normal QRS complex. First-degree AV block is a common finding in patients taking β-blockers, digoxin, nondihydropyridine calcium channel blockers, or other drugs that slow AV conduction (negative dromotropic drugs).

Second-degree heart block consists of two types. Mobitz type I (Wenckebach) is characterized by progressive lengthening of the P-R interval with each beat until an impulse is not conducted; the cycle then starts over again. Mobitz type II (**Fig. 15-8**) impulse conduction is blocked in a fixed, regular pattern (eg, 3:1 block, in which for every three P waves, only one is conducted but each available P-R interval is fixed). A major difference is that Mobitz type I can be induced by negative dromotropic drugs but not Mobitz type II.

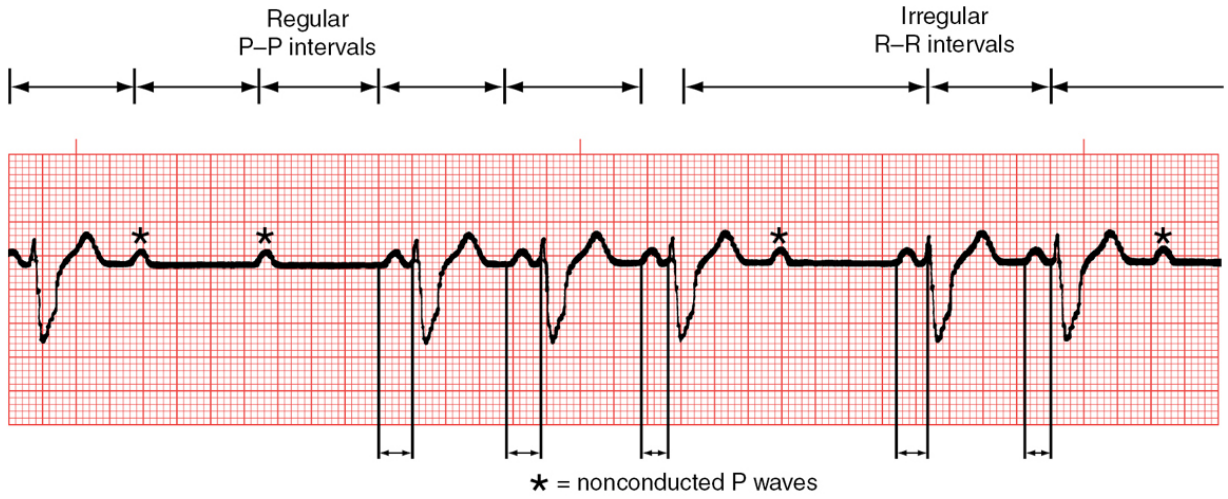

Figure 15-8 Sinus rhythm with second-degree AV block, type II; note constant PR interval. (Reprinted with permission from Smeltzer SC, Bare BG. *Textbook of Medical-Surgical Nursing*. 9th ed. Lippincott Williams & Wilkins; 2000.)

Third-degree heart block (complete heart block) occurs when none of the impulses from the SA node are conducted to the ventricles. During the third-degree block, the ventricle must develop its own pacemaker (escape rhythm), which may be too slow to provide adequate cardiac output, causing the patient to become symptomatic. A mechanical pacemaker is needed for the treatment of permanent third-degree AV block. AV blocks can be caused by negative dromotropic drugs, acute MI, amyloidosis, and congenital abnormalities.[84] Both second and third-degree AV blocks are usually symptomatic ranging from dizziness to unconsciousness. Second- or third-degree AV block with an acute inferior zone (bottom of the

ventricle) MI usually resolves on its own over time, but symptomatic cases can be acutely treated with aminophylline.[84]

Atropine

Case 15-5, Question 2: How should H.T.'s heart block be treated?

H.T. is experiencing a Wenckebach rhythm with compromised hemodynamics and symptoms. Metoprolol should be held and atropine 0.5 mg IV bolus (maximum 2 mg), β-agonists (isoproterenol, dobutamine, and epinephrine), or a temporary pacemaker can acutely increase the heart rate. Once the issue resolves, the dose of metoprolol could be reduced or β-blockers could be stopped altogether, but this could attenuate the mortality benefits postmyocardial infarction. Therefore, according to the guidelines, a permanent pacemaker should be inserted to control the heart rate while maintaining metoprolol therapy.[84]

VENTRICULAR ARRHYTHMIAS

Recognition and Definition

Impulses from ventricular ectopic foci or reentrant circuits generate wide QRS complexes leading to PVCs (**Fig. 15-9**). Three consecutive PVCs that have the same shape usually are defined as monomorphic VT, which can be nonsustained or sustained.

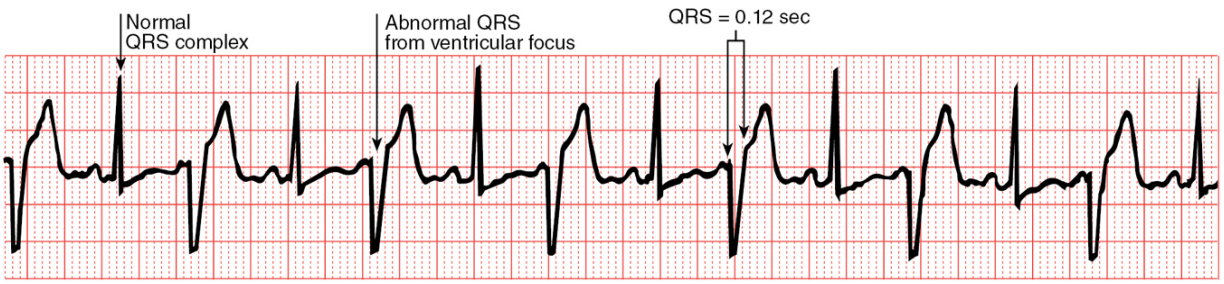

Figure 15-9 Premature ventricular contraction. Every other beat is a premature ventricular (ectopic) contraction.

Nonsustained ventricular tachycardia (NSVT) (**Fig. 15-10**) is commonly defined as three or more consecutive PVCs lasting <30 seconds and terminating spontaneously. Sustained VT (SuVT) is defined as consecutive PVCs lasting more than 30 seconds, with a rate usually in the range of 150 to 200 beats/minute. P waves are lost in the QRS complex and are indiscernible. SuVT (**Fig. 15-11**) is a serious development because it can degenerate into VF. VF (see **Fig. 15-12**) is characterized by irregular, disorganized, rapid beats with no identifiable P waves or QRS complexes. It is thought to be triggered by multiple reentrant wavelets in the ventricle. There is no effective cardiac output or pulse in patients with VF.[85,86]

Figure 15-10 Nonsustained ventricular tachycardia. (Reprinted with permission from MacDonald MG, Seshia MMK, Mullet MD. *Avery's Neonatology Pathophysiology & Management of the Newborn*. 6th ed. Lippincott Williams & Wilkins; 2005.)

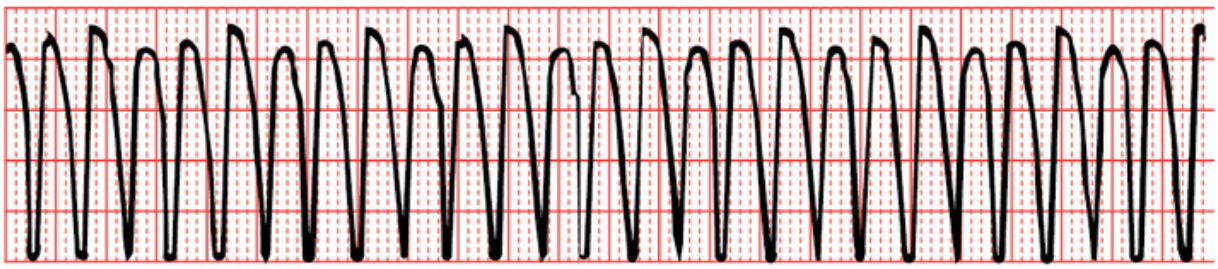

Figure 15-11 Sustained ventricular tachycardia.

Figure 15-12 Ventricular fibrillation.

Etiology

Common factors that cause VT or VF are ischemia, the presence of organic heart disease, exercise, metabolic or electrolyte imbalance (eg, acidosis, hypokalemia or hyperkalemia, hypomagnesemia), or drugs (digitalis, sympathomimetic amines, antiarrhythmic drugs). It is essential to identify and remove any treatable cause (eg, metabolic or electrolyte imbalance and proarrhythmic drugs) before initiating antiarrhythmic drug therapy.

Evaluation Potentially Serious Ventricular Arrhythmias

An episode of life-threatening ventricular arrhythmia (ie, SuVT, TdP, VF) carries a significant risk of morbidity and mortality. Adequate documentation of the arrhythmia and its suppression by either drugs or a mechanical device are essential. The American College of Cardiology (ACC)/American Heart Association (AHA)/Heart Rhythm Society (HRS) guidelines for ventricular arrhythmias specifies that patients suspected of having, or documented to have, symptoms of a life-threatening arrhythmia (eg, syncope, out-of-hospital cardiac arrest) should be admitted to the hospital and evaluated.[85] A 12-lead ECG should be acquired in all patients undergoing evaluation for the presence of ventricular arrhythmias, prior MI (pathologic Q-waves), and long QTc intervals. Echocardiography is also conducted to detect the presence of ventricular wall thickness and structure and to assess valve function and ejection fraction. Ambulatory rhythm

monitoring and EP studies are two additional approaches used to evaluate the arrhythmia and the effectiveness of therapy.[85]

AMBULATORY MONITORING AND ELECTROPHYSIOLOGY STUDIES

Small ECG rhythm recorders called Holter monitors or Loop Recorders are worn by patients, and electrodes are attached to the chest. For more frequent arrhythmia occurrences, 48-hour Holter monitoring is an option. For less frequent arrhythmias, a 30-day Loop recorder can be used instead. Whenever a patient experiences symptoms, they press a button on the recorder and a record of the patient's heart rhythm at the time of the event is recorded. In both cases, the patient logs the symptoms they felt around the time of events.[85]

ELECTROPHYSIOLOGIC STUDIES

EP studies represent another approach to evaluating ventricular arrhythmias, especially in patients with infrequent ventricular arrhythmias that may be missed by ambulatory monitoring.[85] EP testing uses an inserted temporary pacemaker to try to induce arrhythmias which can be important in assessing the need for an implantable cardioverter-defibrillator (ICD).

Premature Ventricular Contractions and Nonsustained Ventricular Tachycardia

CASE 15-6

QUESTION 1: A.S., a 56-year-old female, is admitted to the critical care unit (CCU) with a diagnosis of acute anterior wall MI. Her vital signs are BP, 115/75 mm Hg; pulse, 85 beats/minute; and respiratory rate, 15 breaths/minute. Auscultation of the heart reveals an S_3 gallop. Her electrolytes include potassium (K) 3.8 mEq/L, and magnesium (Mg) 1.2 mEq/L. Otherwise, her examination is within normal limits. Two days later, an echocardiogram estimates her ejection fraction to be 35% (normal, >50%). During her stay in the

CCU as well as the step-down unit, multiple PVCs (15/minute) were noted on the bedside monitor.

Should A.S.'s multiple PVCs be treated with a class I antiarrhythmic drug?

PVCs are a benign, natural occurrence, even in a healthy heart, and are not an indication for class I or class III drug therapy even in patients with other cardiac diseases. However, the presence of frequent PVCs may be associated with concomitant ischemia and impaired left ventricular function, and this should be further explored.[85,87]

TYPE IC ANTIARRHYTHMIC AGENTS

The National Institutes of Health launched the Cardiac Arrhythmia Suppression Trial (CAST)[88,89] to assess the benefit of PVC suppression in survivors of MI. The CAST was a prospective, randomized, placebo-controlled trial that evaluated the class Ic agents flecainide and encainide versus placebo. Ten months after initiation of the study, CAST was discontinued because total mortality in the flecainide and encainide groups was 8.3% compared with 3.5% in the placebo group.[88] Because the patients enrolled in CAST were asymptomatic and at low risk for the development of SuVT, the risk from drug toxicity exceeded the benefit. Thus, the decision to avoid using a class I antiarrhythmic medication to treat A.S.'s PVCs was a sound one.[88,89]

CASE 15-6, QUESTION 2: What alternatives to class I antiarrhythmic drugs should be considered for A.S.?

A-BLOCKING AGENTS

Since A.S. has had an MI, β-blockers have proven benefits. In pooled analyses of numerous trials evaluating β-blockers in MI, ~20% reductions in the risks of reinfarction and cardiac arrest resulted (see Chapter 13, Acute Coronary Syndrome).[90–92] β-Blockers can modestly suppress PVCs in many patients, but only 10% to 15% of them achieve >90% PVC suppression.

In addition, because her ejection fraction is <40%, β-blockers, ACE inhibitors or angiotensin-receptor blockers (with or without neprilysin inhibitor), and aldosterone receptor antagonists—a drug from each class should be given to reduce her risk of overall mortality and Sudden Cardiac Death (SCD).[85]

CASE 15-6, QUESTION 3: While receiving carvedilol 25 mg twice daily, lisinopril 40 mg daily, and eplerenone 25 mg daily for 6 days, A.S. begins to develop nonsustained runs of VT intermingled with the frequent PVCs. The NSVT causes some palpitations but no other symptoms. Are there any additional drugs that should be added to the regimen as a result?

AMIODARONE AND RANOLAZINE

NSVT has a greater risk of inducing SuVT or VF than would PVCs, and this requires further workup and potential therapy.

In high-risk patients with MI who are not candidates for β-blockade, alternative antiarrhythmic therapy with amiodarone can be considered.[93,94] Amiodarone is a class III antiarrhythmic agent but also has antiadrenergic, class I, and class IV activities. However, given that cumulative exposure to this drug can result in damage to multiple organs, caution should be exercised before using it for PVC suppression or NSVT. An evaluation of amiodarone in post-MI patients with frequent PVCs (≥10/hour) or at least one run of VT was conducted in the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT).[93] In this trial, amiodarone significantly reduced the incidence of VF or arrhythmic death by 48.5% compared with placebo. Arrhythmic death alone was reduced by 32.6%, and all-cause mortality was reduced by 21.2%, but these differences were not statistically significant.

Similarly, the European Myocardial Infarct Amiodarone Trial (EMIAT) evaluated MI survivors with a reduced ejection fraction (<40%).[94] Amiodarone significantly reduced arrhythmic deaths by 35% compared with placebo, but no difference in mortality (13.86% with amiodarone vs 13.72% with placebo) was seen.

Ranolazine is a novel antianginal drug that does not reduce BP or heart rate but like amiodarone, possesses both class I and III

antiarrhythmic mechanisms. It is a much safer option than amiodarone for long-term administration. Unfortunately, some trials found no antiarrhythmic benefits whereas others found reductions in VT occurrence but not for SCD.[85]

Ranolazine would be a reasonable additional option for A.S.'s NSVT and frequent PVCs but only if she would benefit from an additional antianginal drug. Although amiodarone might provide more potent antiarrhythmic benefits than ranolazine, given the asymptomatic nature of these NSVT events, the adverse event profile of amiodarone would preclude its use in this patient. However, if the β-blocker could not be used, substituting amiodarone would be reasonable for A.S. Of course, if the patient has hypokalemia and hypomagnesemia, treating these underlying triggers for arrhythmias is worthwhile, but using these therapies just to attempt to suppress NSVT or PVCs is not successful and is not warranted.[85]

Catheter ablation

A better option for A.S. might be the use of ablation. The most commonly employed technique involves activation mapping, where electrophysiologists maneuver catheters to target the precise PVC origin in the heart, which is subsequently heated (radiofrequency ablation) or frozen (cryoablation) destroying the foci.[86–88] Catheter ablation is not without risk but has been shown to abolish PVCs in 74% to 100% of patients in numerous studies.[86–88] Catheter ablation is indicated for patients with reversible left ventricular dysfunction associated with frequent PVCs/NSVT, who have failed, did not tolerate, or declined medical treatment.[87]

A.S. should see an electrophysiologist to determine whether ablation is an option and to be risk stratified for SCD risk. If the risk of SCD is sufficiently high, an ICD should be placed.

Sustained Monomorphic Ventricular Tachycardia

TREATMENT

CASE 15-7

QUESTION 1: S.L., a 64-year-old female, presents to the ED with a palpitations. Her medical history includes hypertension controlled with a diuretic and an inferior wall MI 6 months ago. She is pale and diaphoretic but able to respond to commands. Her vital signs are weight, 138.89 pounds (63 kg); BP, 95/70 mm Hg; pulse, 145 beats/minute; and respiratory rate, 10 breaths/minute. When telemetry monitoring is established, S.L. is found to be in SuVT (Fig. 15-11). S.L.'s echocardiography (6 months earlier) revealed a left ventricular ejection fraction (LVEF) of 32%.

How should she be treated?

Acutely, S.L. could either receive an IV antiarrhythmic drug or undergo DC cardioversion to rapidly convert the patient back to sinus rhythm. Only patients who are hemodynamically stable should receive the antiarrhythmic option while the electrical cardioversion option can be used in either case although a short-acting benzodiazepine (eg, midazolam) should be administered before undergoing DC cardioversion.

Antiarrhythmic agents

Most hemodynamically stable patients with SuVT should receive IV procainamide as first-line therapy with IV amiodarone or sotalol reserved for refractory or recurrent cases.[95] In the randomized, open-label PROCAMIO (PROCainamide-AMIOdarone) trial, patients with SuVT received intravenous procainamide (10 mg/kg/20 minutes) or amiodarone (5 mg/kg/20 minutes). The primary end point (incidence of major cardiac adverse events within 40 minutes) occurred in 9% of procainamide and 41% of amiodarone patients (P = .006), and VT terminated within 40 minutes 67% of procainamide and 38% of amiodarone patients (P = .026).[95]

Procainamide is optimally loaded at 10 to 17 mg/kg infused at 20 to 50 mg/minutes. IV amiodarone should be loaded as a 150-mg dose for 10 minutes, followed by a 6-hour infusion at a rate of 1 mg/minute, and finally a 0.5-mg/minute infusion for 18 hours. Prolonged amiodarone infusions must be in D5W, not normal saline or lactated ringers, and must be in glass or polyolefin bags, not

polyvinyl chloride parenteral bags. For recurrent or resistant arrhythmias, supplemental infusions of 150 mg can be repeated every 10 minutes, up to a maximal total daily IV dose of 2.25 g.[125] IV sotalol 1.5 mg/kg should be infused over 5 minutes.[85] IV sotalol is approximately dose-equivalent to the oral formulation because an IV dose of 75 mg equals an 80-mg oral dose.[85] Commonly seen adverse effects for all three antiarrhythmic agents include hypotension, bradycardia, and AV block, which can be attenuated by slowing the drug infusion rate, but this can also reduce their efficacy. The propensity of sotalol to induce TdP is covered later in this chapter, but QTc interval monitoring after the infusion is important.

If this is unsuccessful and the cardiologist determines that the patient meets the criteria for idiopathic VT without structural heart disease, then intravenous β-blockers or verapamil can be utilized. Additionally, if the cardiologist determines or it is known that the patient has one of many genetically determined arrhythmia syndromes, then the specific therapy for that particular syndrome can be used (such as the selective use of quinidine in Brugada syndrome). Given the number of these syndromes and the complexity associated with their determination, they are outside the scope of this chapter but can be found within the ACC/AHA/HRS ventricular arrhythmia guidelines. A team-based approach to care is essential in complex arrhythmias with the pharmacist guiding the safe use of the drugs (drug dosing, interactions, and incompatibilities) and conducting drug monitoring.[85] S.L. received a 600-mg loading dose of procainamide over 30 minutes and converted back to normal sinus rhythm. She remains on a maintenance infusion of 2 mg/minutes while chronic therapeutic options are considered.

Implantable Cardiac Defibrillators

Case 15-7, Question 2: The next day, S.L. experiences another run of VT lasting about 2 minutes. The cardiology consult service has recommended the placement of an ICD. What is an ICD, and how does it work?

Transvenous or subcutaneous ICDs are devices implanted under the skin with wires or patches that are advanced or attached so they are in direct contact with the ventricular myocardium. The ICD is composed of a pulse generator, sensing and pacing electrodes, and defibrillation coils. The pulse generator consists of a microprocessor, a memory component capable of storing ECG data, a high-voltage capacitor, and a battery. The microprocessor controls the analysis of cardiac rhythm and delivery of therapy.[96,97] When NSVT is detected and then terminates, the ICD will turn on a pacemaker to pace at a rapid rate to overdrive and therefore suppress the ectopic foci. This can prevent the subsequent event (which could be SuVT or VF from arising). If SuVT or VF is detected, the device charges and then induces a period of asystole by shocking it, which hopefully restores normal sinus rhythm. Defibrillation threshold is classified as the minimum amount of energy needed to successfully defibrillate the heart and restore normal sinus rhythm.

Multiple clinical trials have proven the superiority of ICD treatment over antiarrhythmic therapy for the prevention of SCD.[85] ICD therapy is indicated for (a) survivors VF or hemodynamically unstable SuVT; (b) patients with LVEF ≤35% caused by a prior MI who are ≥40 days after the event and are in NYHA functional class II or III; (c) patients with LVEF ≤30% caused by prior MI who are ≥40 days after the event and are in NYHA functional class I; (d) patients experiencing spontaneous SuVT in conjunction with structural heart disease, regardless of hemodynamic stability; (e) hemodynamically compromised patients with electrophysiology study–induced SuVT or VF associated with syncope of undetermined origin; (f) patients with LVEF ≤35% associated with nonischemic dilated cardiomyopathy and are in NYHA functional class II or III; and (g) patients with LVEF ≤40% in conjunction with NSVT secondary to prior MI, who experience SuVT or inducible VF at EP study.[85]

Although ICDs have been shown to improve survival in select patient populations, the benefit may be offset by the diminished quality of life associated with painful shocks, increased mortality compared with ICD patients who do not require shocks, and incomplete protection from the occurrence of SCD (5% of patients

fail to respond).[98–102] In recent years, investigators have examined various approaches to reducing the frequency of ICD shocks. Antiarrhythmic medications and prophylactic catheter ablation have been shown to reduce the incidence of ICD firing.[98–102]

Clearly, S.L. should have an ICD implanted for the category (d) above. An MI meets the definition of structural heart disease (as does HF and left ventricular hypertrophy). It is her best chance for prolonging long-term survival.

Amiodarone

Case 15-7, Question 3: S.L.'s cardiologist would like to start amiodarone as adjunctive therapy because S.L. has expressed concern about the number of ICD discharges that may occur after ICD placement. If S.L. is to be treated with amiodarone, how should it be initiated and monitored?

Although the ICD helps the patient live longer than antiarrhythmic drugs, they are commonly used together. ICD shocks are exquisitely painful and can reduce the quality of life or even cause generalized anxiety and agoraphobia when the shock occurs too frequently.

The OPTIC (Optimal Pharmacological Therapy in Cardioverter Defibrillator Patients) trial enrolled 412 patients with an LVEF <40% who had inducible VT or VF, prior history of SuVT, VF, or cardiac arrest, or syncope of unknown cause with VF or VT. The effect of amiodarone plus β-blocker (metoprolol, carvedilol, or bisoprolol) compared with sotalol or β-blocker alone on the primary end point, the first occurrence of any shock delivered by the ICD, was assessed for a median of 359 days. One-year shock rates were 10.3%, 24.3%, and 38.5%, respectively, in amiodarone/β-blocker–treated patients, sotalol-treated patients, and β-blocker–treated patients, respectively. Of note, adverse effects such as pulmonary toxicity, thyroid effects, and symptomatic bradycardia contributed to an 18.2% discontinuation rate for amiodarone at 1 year. However, longer-term studies assessing the safety and efficacy of amiodarone for secondary prophylaxis showed higher rates of VT recurrence and

major adverse effects, compared with placebo.[121,122] Dofetilide[123] (off-label use) and the combination of mexiletine and amiodarone have shown reductions in recurrences of SuVT in other studies.[99]

Amiodarone exhibits properties of classes I, II, III, and IV antiarrhythmic agents. Although it has class II effects on the heart, amiodarone is virtually devoid of antiadrenergic effects outside the heart and is not contraindicated in patients with asthma. The antiadrenergic effects arise from inhibition of adenylate cyclase, the enzyme that catalyzes the production of the second-messenger product cyclic adenosine monophosphate.[2]

Because of the extremely long half-life of amiodarone, loading doses are used to accelerate the onset of the drug effect. The OPTIC trial used a loading dose of oral amiodarone 400 mg, given twice daily for 2 weeks, followed by a daily dose of 400 mg for the next 4 weeks, and a daily maintenance dose of 200 mg thereafter.[99] A concentration–effect relationship is hard to determine for amiodarone, given its complex pharmacokinetics.

Amiodarone has many serious adverse effects involving a variety of organ systems, the most serious and life-threatening of which is pulmonary toxicity. Amiodarone-induced pulmonary toxicity (AIPT) has been shown to account for 11% of the sum total of all reported adverse events associated with this agent.[103] AIPT presents as an acute process or a chronic condition that develops several months after starting amiodarone therapy. The pathophysiologic mechanism for AIPT has not been fully elucidated but may involve (a) heightened extracellular expression of β-hexosaminidase; (b) imbalance between T-helper 1 and 2 cells, leading to a maladaptive immune response; (c) increased tumor necrosis factor-α activity; and (d) angiotensin-mediated apoptotic effects of amiodarone on alveolar epithelial cells. It has been suggested that higher doses of amiodarone, older age, and preexisting pulmonary disease may predispose patients to develop AIPT. However, AIPT has been shown to occur after patients received low doses of amiodarone (200 mg/day). Manifestations of chronic AIPT include cough, dyspnea, impaired diffusion capacity of carbon monoxide, infiltrates on chest radiograph, weight loss, and fever. In contrast, patients presenting

with acute AIPT experience rapid decline in respiratory function, potentially culminating in the development of acute respiratory distress syndrome (ARDS) with alveolar opacities. Given the prolonged half-life of amiodarone, symptom resolution will be a slow process for patients with AIPT. Patients presenting with marked radiographic opacities and hypoxemia may need to receive prednisone 40 to 60 mg daily for several months. Mortality rates for patients with AIPT have been shown to approach 10%, with higher mortality rates seen in patients requiring hospitalization (20%–30%) or who develop ARDS (50%).[103]

A baseline chest radiograph and pulmonary function tests (diffusion capacity in particular) are recommended by the manufacturer. The chest radiograph should be repeated at 3- to 6-month intervals, and patients should be specifically questioned about pulmonary symptoms because early detection can decrease the extent of lung damage.

Liver toxicity can range from an asymptomatic elevation of transaminases (two to four times normal) to fulminant hepatitis. The mean latent period between the start of amiodarone therapy and evidence of liver injury is 10 months (onset can be as short as 3–4 days), but with rapid IV loading of amiodarone, a Reye syndrome–like fulminant hepatitis can occur as early as 1 day after starting therapy, most likely caused by the IV vehicle polysorbate-80. The precise mechanism of amiodarone-induced hepatotoxicity has not been fully elucidated. However, higher doses and prolonged drug use appear to place patients at higher risk of experiencing hepatotoxic effects of amiodarone. Thus, liver enzymes should be monitored at baseline, 1, 3, 6 months, and semiannually afterward.[104,105] The most common GI symptoms are nausea, anorexia, and constipation, which occur in 25% of patients receiving amiodarone.

Both hypothyroidism and hyperthyroidism have been reported, although hypothyroidism is more common. The thyroid complications are a consequence of amiodarone's large iodine content and its ability to block the peripheral conversion of thyroxine (T_4) to

triiodothyronine (T_3). In addition, amiodarone and its metabolite, desethylamiodarone, appear to be directly cytotoxic to the thyroid gland.[106]

Recent reports have indicated that photosensitive eruptions occur in 7% of amiodarone recipients.[107] Classical presentations of amiodarone photosensitivity involve a burning and tingling sensation in sun-exposed skin with accompanying erythema. Approximately 1% to 2% of patients receiving amiodarone for long-term use develop blue-gray pigmentation on sun-exposed skin. Resolution of amiodarone-associated photo-induced pigmentation may take up to 2 years, with gradual fading of skin discoloration.[107] In recent years, amiodarone-associated optic neuropathy has been highlighted in multiple case reports. A review of amiodarone-associated optic neuropathy (January 1993–May 2011) revealed a total of 214 cases from the FDA's Adverse Event Reporting System, 59 published cases, and 23 cases from clinical trials.[144] On average, patients received amiodarone for 9 months (range 1–84 months) before experiencing vision loss. In 20% of cases, patients progressed to legal blindness in at least one eye. Other bothersome side effects are corneal deposits (usually asymptomatic), exacerbation of HF, and central nervous system effects that include ataxia, tremor, dizziness, and peripheral neuropathy. Other than eye examination and pulmonary function tests, which should be repeated when the patient is symptomatic, other tests should be repeated every 6 months (thyroid and liver function) or annually (chest x-rays) for routine monitoring.[108] Amiodarone also blocks multiple cytochrome P-450 enzyme systems and P-glycoprotein pumps, resulting in clinically significant drug interactions.

CASE 15-7, QUESTION 4: S.L. is placed on amiodarone and dosed according to the OPTIC trial. After two months, the patient starts to get breakthrough NSVT and SuVT events requiring overdrive pacing or ICD shocks one to three times a week for 3 consecutive weeks. It is seriously reducing the patient's quality of life. What should be done to prevent this from occurring as often?

The VANISH (Ventricular Tachycardia Ablation versus Escalated Antiarrhythmic Drug Therapy in Ischemic Heart Disease) trial included patients with an ICD who had VT despite the use of antiarrhythmic drugs.[109] Patients were randomized to catheter ablation with continuation of baseline antiarrhythmic medications or escalated antiarrhythmic drug therapy. In the escalated therapy group, amiodarone was substituted if another agent had been used previously. If amiodarone was used previously, the dose was increased to 300 mg/day or, if the dose was already at least 300 mg/day, mexiletine was added. The primary outcome (composite of death, three or more documented episodes of VT within 24 hours [VT storm], or appropriate ICD shock) occurred in 59.1% of patients in the ablation group and 68.5% of those in the escalated therapy group (P = .04). In subgroup analysis, those patients who initially failed amiodarone did better with ablation while those failing other therapy who were switched to amiodarone did similarly as well. One confounder is that the ablations were performed in major medical centers with experienced electrophysiologists, which might have maximized the benefits versus procedures done in hospitals with lower ablation procedure volumes.[109]

Because S.L. had failed amiodarone therapy at 200 mg, it is likely that an ablation procedure with an experienced electrophysiologist would provide superior efficacy to amiodarone dosage elevation or the addition of mexiletine.

Torsades de Pointes

PROARRHYTHMIC EFFECTS OF ANTIARRHYTHMIC DRUGS AND CLINICAL PRESENTATION

CASE 15-8

Question 1: L.G. is a 69-year-old female who is taking sotalol 80 mg twice daily for a previous episode of SuVT. L.G. was admitted to the hospital 3 days ago for altered mental status. She is also taking oral citalopram 40 mg every morning for major depressive disorder. At baseline, her QTc interval was 400

milliseconds, and her CrCl was 50 mL/minute. Other laboratory values are as follows:

Potassium, 4.0 mmol/L
Blood urea nitrogen (BUN), 32 mg/dL
Serum creatinine, 1.5 mg/dL

Today, her ECG reveals a QTc interval of 502 milliseconds and TdP, with a ventricular rate of 110 beats/minute.

What is QTc interval prolongation? Why does QTc interval prolongation indicate an increased risk of TdP? Could an antiarrhythmic agent such as sotalol cause this arrhythmia?

How does CrCl affect this?

The QT interval denotes ventricular depolarization (the QRS complex in the cardiac cycle) and repolarization (from the end of the QRS complex to the end of the T wave). Certain ion channels in phases 2 and 3 of the action potential are vital in determining the QT interval (see Fig. 15-1). An abnormal increase in ventricular repolarization increases the risk of TdP. TdP is defined as a rapid polymorphic VT preceded by QTc interval prolongation. TdP can degenerate into VF and as such can be life-threatening (**Fig. 15-13**).[110]

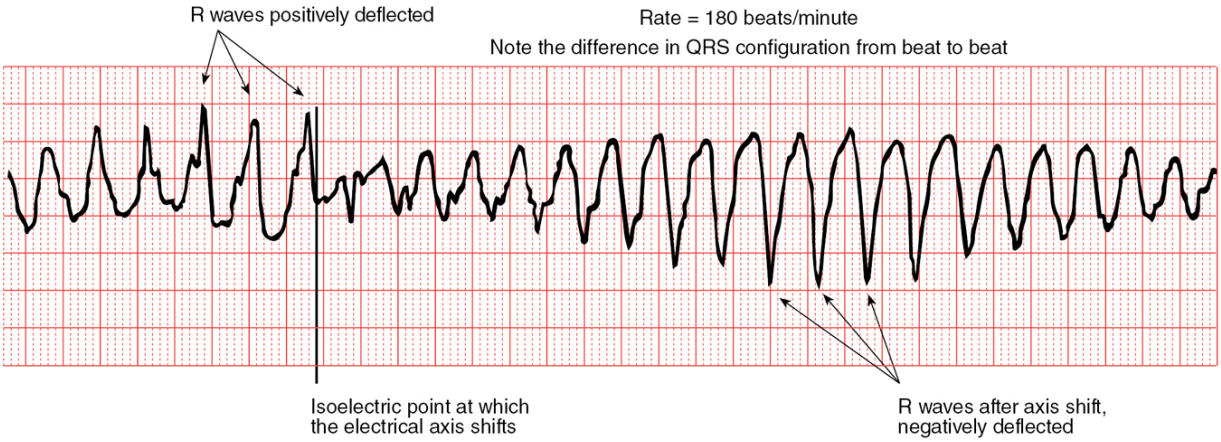

Figure 15-13 Torsades de pointes.

Because there is tremendous variability in the QT interval resulting from changes in heart rate, the QT is frequently corrected for heart rate (QTc interval). Several correction formulas for the QT interval exist and give similar results at most heart rates. The most common

correction formula uses QT and R–R intervals measured in seconds as follows: (QTc − QT/[R–$R^{0.5}$]). However, overcorrection of the QT interval may occur in persons with elevated heart rates (>85 beats/minute).[111,112] The Fridericia correction (QTc − QT/ [R–$R^{1/3}$]) represents an alternative correction method for patients with heart rates exceeding 85 beats/minute.

Any QTc interval over 500 milliseconds is a definite risk factor for the development of TdP as is an increase from the baseline QTc interval by 60 milliseconds. Increases from baseline of 30 to 60 milliseconds is a moderate risk factor for developing TdP.[110–112]

Class Ia and class III antiarrhythmic agents have been shown to induce TdP in numerous literature reports.[110,111] Of note, class Ia antiarrhythmic agents do not exhibit dose-dependent association with TdP, whereas the incidence of TdP does appear to be dose related with class III antiarrhythmic agents. QT prolongation associated with the use of class Ia antiarrhythmic agents is likely the result of blockade of outward potassium channels, but it is offset by concomitant blockade of inward sodium channels at increased drug concentrations.[2,113] TdP induced by class III antiarrhythmic agents arises from prolonged repolarization and cardiac refractoriness. All class III antiarrhythmic agents have been implicated in cases of TdP, although amiodarone and dronedarone are less likely to do so than the others.[2,114] These drugs block both multiple potassium channels, not just the rapid component of the delayed rectifier potassium channel (IKr) in the ventricle. This causes less transmural dispersion of repolarization from the endocardium, midmyocardium, and epicardium and is noted by less prolongation from the peak of the T wave to the end of the T wave (T_{peak} to T_{end}).[115]

Class Ic antiarrhythmic agents do not exert significant effects on repolarization and therefore have rarely been shown to induce TdP in patients without structural heart disease. To date, eight cases of flecainide-induced TdP have been published, along with one report of propafenone-associated TdP.[116–118]

Sotalol is known to cause QTc interval prolongation in a dose-dependent manner. Total daily doses of 160, 320, 480, and >640 mg

gave patients a steady-state QTc interval of 467, 473, 483, and 512 milliseconds, and the incidence of TdP was 0.5%, 1.6%, 4.4%, and 5.8%, respectively.

It is likely that L.G.'s reduced renal function put her at high risk for sotalol accumulation and accentuated QTc interval prolongation. In patients with a CrCl >60 mL/minute, the sotalol dose of 80 mg twice daily is appropriate, but in patients like L.G. with a CrCl <40 to 60 mL/minute, the manufacturer-recommended dose should be 80 mg daily or 40 mg twice daily owing to sotalol's predominant renal clearance.

Hypokalemia, hypomagnesemia, hypocalcemia (rare cases of TdP), concurrent use of more than one QT-prolonging drug, advanced age, female sex, heart disease (HF or MI), treatment with diuretics, impaired hepatic drug metabolism, and bradycardia are important risk factors for TdP in hospitalized patients.[111,113] Hypokalemia may prolong QT interval by modifying the function of the inwardly rectifying potassium channel, resulting in heterogeneity and dispersion of repolarization. Prolonged ventricular cycle length can assume the form of complete AV block, sinus bradycardia, or a rhythm in which long cycles may progress to arrhythmogenic EAD.

CASE 15-8, QUESTION 2: What transient conditions or other disorders can increase the risk of TdP in patients on class Ia or III antiarrhythmic agents?

Congenital long QT syndrome (LQTS) occurs in 1 in 2500 individuals and is a channelopathy associated with mutations identified in genes encoding voltage-gated sodium and potassium channels.[2,111] Since 1995, ~1000 individual LQTS-causing mutations have been detected in 12 distinct LQTS-susceptibility genes. The LQTS-susceptibility genes *KCNQ1* (encoded I_{Ks} α-subunit), *KCNH2* (encoded I_{Kr} α-subunit), and *SCN5A* (encoded Nav1.5 α-subunit) account for nearly 75% of all congenital LQTS cases.

Because L.G. did not have a family history of hereditary LQTS but was being treated with sotalol (an agent known to be associated with

TdP) in renal dysfunction, it can be assumed that sotalol therapy was responsible for her arrhythmia.

Case 15-8, Question 3: Which nonantiarrhythmic agents cause TdP? What is the mechanism of TdP initiation in this situation?

PROARRHYTHMIC EFFECTS OF NONANTIARRHYTHMIC AGENTS

Nonantiarrhythmic agents can also exhibit potassium channel inhibitory properties and can prolong the QTc interval. Most of these drugs, including arsenic trioxide, macrolide antibiotics, fluoroquinolones, azole antifungals, methadone, antidepressants, organophosphorus compounds, and antipsychotics, cause QTc interval prolongation by inhibiting the IKr potassium ion channel, just like quinidine and sotalol.[119–125] However, ranolazine and pentobarbital block multiple potassium channels like amiodarone and yield a lower TdP risk for each level of QTc interval prolongation.[2,115] Moreover, toxic concentrations of nonantiarrhythmic drugs can induce TdP as a result of large doses, impaired kidney or liver function, or other drug therapy that interferes with the metabolism of nonantiarrhythmic drugs.

The U.S. FDA alerted health care providers about new dosing recommendations for citalopram owing to concerns of QTc interval prolongation and TdP when using this agent at higher doses.[121] Key recommendations included (a) prescribing citalopram at a dose of ≤20 mg/day for patients age >60 years (also, in patients age <60 years with hepatic impairment or taking cimetidine) and (b) prescribing citalopram at a dose of ≤40 mg/day for younger patients. Hasnain and associates recently conducted a comprehensive review of published literature on QTc interval prolongation and/or TdP risk associated with antidepressants and antipsychotics.[122] The authors identified the highest number (16) of case reports implicating citalopram, relative to other antidepressants, including fluoxetine (9), escitalopram (6), venlafaxine (5), and sertraline (2). Quetiapine was the antipsychotic drug with the largest number of QTc interval

prolongation and/or TdP cases (16), followed by ziprasidone (13), risperidone (13), amisulpride, olanzapine (6), and clozapine (5). The authors of the review noted that 92% of patients had at least one additional risk factor for QTc interval prolongation.

During the past two decades, multiple case reports of methadone-induced TdP have been published. Guidelines recommend QTc interval monitoring, but some experts have questioned the necessity of screening patients.[123] Kao et al[123] reviewed the FDA Adverse Event Reporting System (FAERS) database for QTc interval prolongation or TdP events linked with methadone compared to other agents including antiarrhythmic drugs and other opioids. Between 2000 and 2011, the three most commonly implicated drugs were dofetilide (359 cases), methadone (211), and sotalol (119). The authors acknowledged limitations of their analysis (voluntary and selective reporting, along with the inability to determine incidence rates) but suggested that a Risk Evaluation and Mitigation Strategy (REMS) specific to methadone may be warranted to lower the risk of TdP.[124] Like methadone, the natural opioid kratom and massive ingestions of loperamide in patients trying to self-control their opioid addiction has also resulted in QTc interval prolongation and TdP. Naloxone does not treat TdP resulting from these opioid drugs as the IKr channel blockade is a direct action not secondary to opioid receptors.[126–128] Currently, the utility of published cardiac risk data on anti-infective agents is limited, owing to underreporting, failure to completely eliminate contributory confounding variables (cardiac disease, electrolyte abnormalities, use of other QT-prolonging drugs), and the retrospective nature of some postmarketing studies.[119] However, the propensity of antimicrobial agents to induce QT prolongation appears to be specially marked with macrolide antibiotics. All of the commercially available antifungal agents have been shown to induce TdP and QTc prolongation, with a larger number of cases attributed to fluconazole, followed by voriconazole.[125] Among the marketed quinolones in the United States, ciprofloxacin appears to display the lowest potential for causing TdP.[119,125]

A list of nonantiarrhythmic agents implicated in causing QTc interval prolongation and known pharmacokinetic drug interaction increasing the blood concentrations of these drugs is given in **Table 15-6**.

Table 15-6
Nonantiarrhythmic Agents With Known Torsades de Pointes Risk[a]

Drug Class	Agent	Drugs That Increase Blood Concentrations of These QTc Interval–Prolonging Drugs
Anesthetic, general	Propofol, sevoflurane	
Antibiotics: macrolides	Azithromycin, clarithromycin, erythromycin (lactobionate and base)	
Antibiotics: fluoroquinolones	Ciprofloxacin, levofloxacin, moxifloxacin	
Antibiotics: other	Pentamidine isethionate	
Anticancer	Arsenic trioxide, vandetanib	
Antidepressants	Citalopram, escitalopram	CYP3A4 or 2C19 inhibitors
Antiemetics	Chlorpromazine, droperidol, ondansetron	CYP3A4 (primary for ondansetron), 1A2 (primary for chlorpromazine), or 2D6 inhibitors
Antifungals	Fluconazole	
Antimalarials	(Hydroxy)chloroquine, halofantrine	Cimetidine (chloroquine), CYP3A4 inhibitors (halofantrine)
Antipsychotics	Haloperidol, pimozide, thioridazine	CYP2D6 (thioridazine) or 3A4 (pimozide) inhibitors
Cholinesterase inhibitors	Donepezil	CYP3A4 or 2D6 inhibitors

Narcotics	Methadone, mega-dose loperamide, kratom	CYP3A4, 2B6, and 2C19 inhibitors
Phosphodiesterase 3 inhibitor	Anagrelide, cilostazol	CYP1A2 (anagrelide), 3A4 (primary for cilostazol), or 2C19 inhibitors

[a]An up-to-date list can be found at http://www.crediblemeds.org/everyone/; Used with permission.

Because L.G. was taking citalopram in combination with sotalol, it is likely that QTc-prolonging effects resulting from concomitant use contributed to the development of TdP.

TREATMENT

Case 15-8, Question 4: How should TdP be treated? What treatments should be considered for L.G.?

If the patient is significantly hemodynamically compromised (frequently associated with a ventricular rate >150 beats/minute, unconsciousness, inability to identify who or where they are) while in TdP, DC cardioversion is the therapy of choice and should be given immediately.

Magnesium

In a hemodynamically stable patient, magnesium is frequently considered the drug of choice to restore normal sinus rhythm. It benefits patients whether they have hypomagnesemia or normal serum magnesium levels. However, magnesium is not effective for patients with polymorphic VT without TdP and with normal QT intervals. Hypokalemia should be corrected, and there is conflicting evidence on the value of achieving potassium levels in the high normal range of 4.5 to 5.0 mmol/L.[129] A common magnesium regimen is 2 g given for 60 seconds through the IV route, followed by an infusion of 2 to 4 mg/minute. The exact mechanism of action for magnesium in TdP is not known, but it reduces the occurrence of triggered activity such as EAD. In addition, magnesium blocks L-type

calcium channels in the membrane and may stabilize the membrane gradient through activation of the sodium–potassium ATPase.[129]

Other treatment options for torsades de pointes

Cardioacceleration with isoproterenol (1–4 µg/minute) or cardiac pacing has also been shown to be beneficial.[130,131] As described previously, the ability of sotalol, quinidine, and *N*-acetylprocainamide to prolong the APD is diminished at faster heart rates (reverse use dependence).[131] The more the inwardly rectifying potassium channels are activated, the less susceptible the channels are to inhibition by potassium channel blocking drugs.

Transvenous pacing is of some use in abolishing refractory TdP.[130–133] Before adjusting the ventricular rate to suppress ectopic ventricular beats, it is essential to ensure proper catheter placement and cardiac capture. In general, ventricular rates of 90 to 110 beats/minute can usually eliminate ventricular ectopy, but some patients may require rates as high as 140 beats/minute. Once control of TdP has been attained, the pacing rate can be gradually decreased to the lowest paced rate that suppresses further ectopy and dysrhythmia.

Numerous other strategies have been utilized for patients who fail to respond adequately to standard therapeutic approaches, including lidocaine and mexiletine, calcium channel blockers, and propofol.[128,134] However, the evidence supporting these alternative agents is not compelling enough to classify them as first-line options for abolishing TdP.

Because L.G. is hemodynamically stable, a bolus injection of 2 g of magnesium should be administered over 1 minute, followed by an infusion administered at a rate of 2 to 4 mg/minute. If the arrhythmia recurs, cardiac pacing should be used.

CARDIOPULMONARY ARREST

Cardiopulmonary Resuscitation

Cardiac arrest from VF, pulseless VT, pulseless electrical activity (PEA), and asystole are life-threatening emergencies. **Table 15-7**[135–140] reviews commonly used drugs for these indications. Health care practitioners treating patients during a cardiac arrest should be Advanced Cardiac Life Support (ACLS) certified. Although this section provides salient information on the diseases, treatments, and mechanisms, the reader should also review the newest national consensus guidelines under construction in 2020 and set for release in 2021.[135]

Table 15-7
Commonly Used Drugs in Cardiac Arrest

Drug	Formulation	Dosage/Administration	Rationale/Indications	Comments
Epinephrine	0.1 mg/mL (1:10,000) or 1 mg/mL (1:1000)	10 mL of a 1:10,000 solution of epinephrine (1 mg; dilute 1:1000 solution in 0.9% sodium chloride) every 3–5 minutes	Increases coronary sinus perfusion pressure through α_1 stimulation Indicated in pulseless VT, VF, asystole, and PEA	If administered through a peripheral catheter, need to flush the line to get the drug into the central compartment.
Amiodarone	50 mg/mL Vials: 3, 9, 18 mL	300 mg diluted in 20–30 mL D5W or NS; an additional 150 mg (diluted solution) can be given for recurrent or refractory VT or VF	Exhibits antiadrenergic properties and blocks sodium, potassium, and calcium channels First-line antiarrhythmic for pulseless VT and VF	Excipients (polysorbate 80 and benzyl alcohol) can induce hypotension. Failing to dilute can induce phlebitis.

D5W, 5% dextrose in water; NS, normal saline; PEA, pulseless electrical activity; VF, ventricular fibrillation; VT, ventricular tachycardia.

Treatment

CASE 15-9

Question 1: M.N., a 52-year-old male, is visiting his wife, who is hospitalized for pneumonia. His past medical history is significant for hypertension and type 2 diabetes mellitus. He goes into the bathroom, and 2 minutes later his wife hears a dull thud. She calls out for her husband, but he does not respond. After an additional 2 minutes, health care workers open the bathroom door and find M.N. unresponsive and pulseless. CPR is initiated and a code blue is called. The ECG shows VF (Fig. 15-12), and there is no BP.

In addition to CPR, what initial therapy is available?

Determining the underlying rhythm disturbance is important because it directs health care workers to follow the ACLS algorithm for pulseless VT or VF. The algorithm calls for electrical defibrillation first, but other clinicians should work to establish IV access in case defibrillation fails.[135]

EXTERNAL DEFIBRILLATION

In VF and pulseless VT, DC cardioversion is the first corrective therapy that is attempted. Although commercially available manual defibrillators provide monophasic or biphasic waveform shocks, the biphasic defibrillator has become the preferred device owing to its high first-shock efficacy.[135] Most commercially available biphasic defibrillators display the device-specific energy dose range that should be used. However, if a health care provider operating a manual biphasic defibrillator is uncertain of the effective energy dose to terminate VF, using the maximal shock energy setting available is preferred. For second and subsequent shocks delivered by manual biphasic defibrillators, the same or higher energies should be used. For first and subsequent shocks, a shock of 360 J should be delivered if a monophasic defibrillator is used to terminate VF.

CASE 15-9, QUESTION 2: The initial shock fails to cause a return of spontaneous circulation in M.N. An IV catheter is established in a peripheral arm vein. What is the first drug that should be used?

EPINEPHRINE

If the patient's defibrillation threshold is above a monophasic 360 J shock, shocking at 360 J will be unsuccessful.[135] Shocking above 360 J might cause more people to convert out of VF or pulseless VT, but it will likely damage the ventricular myocardium so severely that the patient will die from PEA. This is why DC cardioversion machines limit the maximum shock energy.

The first drug strategy seeks to add epinephrine to lower the patient's defibrillation threshold, hopefully below the maximum shock energy the machine can provide. Although epinephrine stimulates

β_1-, β_2-, and α_1-adrenergic receptors, it is the α_1-adrenoceptor effects that are most closely associated with efficacy in VF or pulseless VT.[135] Applying α_1-adrenoceptor stimulation increases systemic vascular resistance (via vasoconstriction), which elevates coronary perfusion pressure and makes the VF waves look more coarse. These features lower the defibrillation threshold.

The recommended dose of epinephrine is 1 mg (10 mL of a 1:10,000 dilution; refer to Table 15-7) given by IV push. The dosage can be repeated at 3- to 5-minute intervals during resuscitation. If the drug is given IV through a peripheral catheter, which in this case includes a peripherally inserted central catheter, then a 20-mL flush with normal saline is recommended to ensure delivery into the central compartment. Only chest compressions cause blood circulation in VF or pulseless VT, so the movement of drugs from the periphery to the heart (where the benefit will occur) is severely impaired.[135]

Case 15-9, Question 3: M.N. is given a 1-mg bolus of epinephrine, followed by a 20-mL normal saline flush. The arm was elevated for 20 seconds to ensure adequate delivery. Thirty seconds after administration, a 200-J shock is given (via biphasic manual defibrillator), but it fails to convert VF. What can be done now?

The most recently updated ACLS guideline calls 2 additional minutes of CPR followed by the use of IV amiodarone or lidocaine in cases of VF or pulseless VT that do not respond to CPR, shocks, and epinephrine.[135] The strategy here is that giving an antiarrhythmic drug will allow a patient who converts but then immediately goes back into VF or pulseless VT to instead maintain Return of Spontaneous Circulation (ROSC) after the shock.

INTRAVENOUS AMIODARONE AND LIDOCAINE

The effect of IV amiodarone on VF or pulseless VT was studied in the ARREST (Amiodarone for Resuscitation of Refractory Sustained Ventricular Tachyarrhythmias) trial.[139] This study was conducted in

patients who experienced cardiac arrest in an out-of-hospital situation with therapy given by paramedics in the field. Patients who failed three stacked shocks and one dose of epinephrine with an electrical countershock were randomly assigned to amiodarone 300 mg IV bolus or placebo. This was followed by other antiarrhythmic agents historically used in ACLS (2000 guidelines: lidocaine, procainamide, or bretylium) if the clinicians desired. Amiodarone significantly increased the chance of survival to hospital admission (44% vs 34% of the placebo group; *P* = .03), but survival to hospital discharge was not changed. Of note, 66% of patients received antiarrhythmic drug treatment for pulseless VT or VF after amiodarone administration.

The ALIVE (Amiodarone vs Lidocaine in Ventricular Ectopy, *n* = 347) trial directly compared IV amiodarone 300 mg to lidocaine 1 to 1.5 mg/kg bolus.[141] In this trial, patients needed to fail three stacked shocks and epinephrine plus an additional shock to be eligible for randomization to either amiodarone or lidocaine. Amiodarone was given as an initial dose of 5 mg/kg followed by a shock. If unsuccessful, a dose of 2.5 mg/kg was given followed by a subsequent shock. Lidocaine was given as a 1.5 mg/kg bolus followed by a shock. If therapy failed, then a second bolus of 1.5 mg/kg was used with a subsequent shock. Patients given amiodarone were 90% more likely to experience survival to hospital admission than those given lidocaine (*P* = .009). Unfortunately, no significant advantage to hospital discharge occurred (5% vs 3%).

On the basis of these findings, amiodarone is preferable to lidocaine in its ability to improve the return of spontaneous circulation and short-term survival. However, it has not yet been shown to improve survival to hospital discharge.

Case 15-9, Question 4: M.N. is given amiodarone 300 mg diluted to 20 mL in D5W and administered with the arm subsequently elevated for 20 seconds. The next DC cardioversion shock was also unsuccessful. What should be done now?

M.N. is at serious risk of death as a result of VF. He should again receive CPR for 2 minutes and then repeat the cycle with epinephrine and if unsuccessful amiodarone 150 mg or lidocaine should be administered. As long as M.N. remains in VF, it is appropriate to continue active therapy. If M.N. degenerates into asystole after more than two or three cycles of treatment for VF, then the resuscitation efforts should be discontinued. However, if a patient only had a brief period of VF before having asystole, it is prudent to apply active asystole therapy.

Pulseless Electrical Activity

CASE 15-10

Question 1: J.D. is an 80-year-old female who experiences cardiac arrest in the hospital. J.D. was in respiratory failure upon admission to the ED, where she underwent immediate intubation, had a peripheral IV placed, and upon transfer to the medical intensive care unit (MICU), placed on assist/control mechanical ventilation with F_{IO_2} of 100%. A rhythm is noted on the monitor, but no femoral pulse is felt. J.D. is in PEA.

How should J.D. be assessed?

PEA is the clinical situation in which there is organized electrical activity on the monitor without a palpable pulse. Although electrical activity is present, it fails to stimulate the contractile process. Virtually, all patients in PEA without an identified treatable cause die. Therefore, it is imperative to rule out treatable causes in patients who appear to be in PEA. The major treatable causes are hypovolemia, hypoxia, acidosis, hyperkalemia, hypokalemia, hypothermia, cardiac tamponade, pulmonary embolism, acute coronary syndrome, trauma, and drug overdose.[135]

Case 15-10, Question 2: No treatable cause of PEA was identified for J.D. What treatment should she receive?

In the absence of an identifiable cause, the focus of resuscitation is to administer high-quality CPR, and after the initial rhythm check, resume CPR during the establishment of IV or intraosseous (IO) access.[135]

Once IV or IO access becomes available, administer epinephrine 1 mg every 3 to 5 minutes.[135,142,143] When the rhythm is PEA or asystole, you do not shock the patient as you can make the chances of survival worse, not better. Shocking could further damage the myocardial muscle in PEA and would promote asystole in the patient who already has this disorder.

Asystole

CASE 15-11

Question 1: K.K., a 73-year-old male, has a past medical history significant for hypertension and diverticulitis. Upon arrival at the operating room for surgical correction of pericardial and pleural effusions, K.K. received etomidate, fentanyl, lidocaine, and succinylcholine. During placement of a double-lumen endotracheal tube, K.K. goes into cardiac arrest. The ECG shows a flat line, and the patient is determined to be in asystole (**Fig. 15-14**).

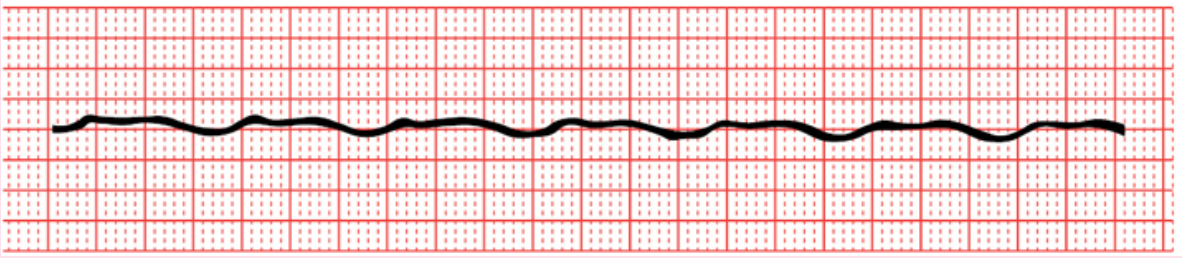

Figure 15-14 Asystole. There is no electrical activity detected in the heart resulting in a very low-amplitude undulating waveform.

Is this rhythm treatable?

Lack of electrical activity or asystole, like PEA, carries a grave prognosis. Its development usually indicates a prolonged arrest, which may explain its poor response to treatment. The tremendous death of myocardial cells with prolonged VF or pulseless VT leaches

out intracellular potassium. This raises the interstitial concentrations above the threshold level for the pacemakers to initiate an electrical depolarization. However, a few patients go directly from a sinus rhythm into asystole and may be resuscitated. Enhanced parasympathetic tone, possibly attributable to a vagal reaction, manipulation of the airway from intubation, suctioning or insertion of an oral airway, or chest compression, may play a role in inhibiting supraventricular and ventricular pacemakers.[136]

A post hoc analysis performed by Wenzel et al[136] demonstrated superior survival rates at the time of hospital admission in vasopressin-treated patients, compared with epinephrine-treated patients. However, no difference in intact neurologic survival was noted between the two treatment groups. Consequently, the guidelines recommend the use of epinephrine 1 mg IV every 3 to 5 minutes with no DC cardioversion.

CASE 15-11, QUESTION 2: Does the timing of epinephrine dosing impact survival to hospital discharge in patients with nonshockable rhythms (asystole or PEA)?

A post hoc analysis of data from the Get With the Guidelines-Resuscitation study showed a stepwise reduction in survival to hospital discharge (primary study end point) with each 3-minute delay to epinephrine: (a) 1 to 3 minutes (odds ratio [OR] 1.0, reference group); (b) 4 to 6 minutes (OR, 0.91; 95% CI, 0.82–1.00; $P = .055$); (c) 7 to 9 minutes (OR, 0.74; 95% CI, 0.63–0.88; $P < .001$); and (d) >9 minutes (OR, 0.63; 95% CI, 0.52–0.76; $P < .001$).[144]

Hypertensive Crises

Sandeep Devabhakthuni, Ryan G. D'Angelo, and Michael Armahizer

CORE PRINCIPLES		CHAPTER CASES
1	Hypertensive crisis is defined as a systolic blood pressure >180 mm Hg and/or diastolic blood pressure >120 mm Hg. This disorder can be further classified as hypertensive urgency or hypertensive emergency when there is evidence of acutely progressive end-organ damage.	**Case 16-1 (Question 1), Table 16-1**
2	Risk factors for the development of a hypertensive crisis include, but are not limited to, medication nonadherence, illicit drug use, and drug–drug and drug–food interactions.	**Case 16-1 (Question 1)**
3	Hypertensive urgency can be treated with oral antihypertensive agents including clonidine, labetalol, or	**Case 16-1 (Questions 2–6), Table 16-3**

	captopril. Caution must be taken to prevent rapid reductions in blood pressure.	
4	The organs primarily affected as a result of a hypertensive emergency are the central nervous system, eyes, heart, and kidneys.	**Case 16-2 (Question 1)**
5	Parenteral therapy should be used to manage hypertensive emergencies, and therapeutic options are dictated by the affected organ(s) and comorbidities. Mean arterial pressure should be reduced by no more than 25% within the first hour, then subsequently reduced toward a goal of 160/100–110 mm Hg, for most patients, during the next 2–6 hours. Gradually reduce blood pressure to normal, for most patients, during the next 24–48 hours.	**Case 16-2 (Questions 2–5, 9, 10)** **Case 16-3 (Questions 1–6)** **Case 16-4 (Questions 1, 2), Tables 16-2 and 16-4, Figure 16-1**
6	Nitroprusside, a therapeutic option for hypertensive emergencies, has been associated with cyanide and thiocyanate toxicity, and monitoring is required to minimize the risk of these toxicities, especially in patients with renal impairment.	**Case 16-2 (Questions 6–8)**
7	The most commonly used agents for the management of postoperative hypertension are nicardipine, clevidipine, nitroglycerin, nitroprusside, and labetalol.	**Case 16-5 (Questions 1–3)**
8	Management of aortic dissection	**Case 16-6 (Question**

requires prompt control of blood pressure without increasing the force of cardiac contraction or heart rate. | 1)

INTRODUCTION

The term *hypertensive crisis* is defined as a systolic blood pressure (SBP) >180 mm Hg and/or diastolic blood pressure (DBP) >120 mm Hg.[1] The actual blood pressure (BP) level may not be as important as the rate of BP rise because patients with chronic hypertension often tolerate higher BP compared to those who are normotensive. These disorders are divided into two general categories: *hypertensive emergency* and *hypertensive urgency* (**Table 16-1**). If left untreated, the 1-year death rate associated with hypertensive emergencies is >79%, and median survival is 10.4 months.[1–5]

Table 16-1
Hypertensive Emergency Versus Urgency

	Emergency	Urgency
Blood pressure criteria	Systolic > 180 mm Hg[a] Diastolic > 120 mm Hg[a]	
Life-threatening	Potentially	Not acutely
End-organ damage	Acute or progressing	Chronic; not progressing
Clinical manifestations	CNS (dizziness, N/V, encephalopathy, confusion, weakness, intracranial or subarachnoid hemorrhage, acute ischemic stroke) Eyes (ocular hemorrhage or funduscopic changes, blurred vision, loss of sight) Cardiac (left ventricular failure, pulmonary edema, MI, angina, aortic dissection)	Optic disc edema

	Renal failure or insufficiency	
Treatment strategy	Immediate reduction in blood pressure within hours; administer parenteral therapy (Table 16-2)	Reduction in blood pressure over several hours to days; administer oral therapy (Table 16-3)

CNS, central nervous system; MI, myocardial infarction; N/V, nausea and vomiting.

[a]Degree of blood pressure elevation is less diagnostic than the rate of pressure rise and presence of concurrent diseases or end-organ damage. See Chapter 9, Essential Hypertension, for staging of hypertension.

The term *hypertensive emergency* describes a clinical situation in which the elevated BP has caused acute progressive secondary organ damage (eg, stroke or myocardial infarction [MI]). Admission to an intensive care unit is recommended for rapid reduction in BP to a safe level (not necessarily normal) within minutes to hours.[1] *Hypertensive urgency* is not an immediately life-threatening situation; a reduction in BP to a safe level can occur more slowly over the next 24 to 48 hours.[1,6]

Acute, potentially life-threatening elevations of BP can occur in previously normotensive individuals with acute glomerulonephritis, head injury, or severe burns; during pregnancy (eclampsia); and with the use of recreational drugs such as cocaine. Other causes include abrupt medication withdrawal or medication nonadherence, drug–drug interactions (including herbal medications), erythropoietin administration, or drug–food interactions (ie, patients receiving monoamine oxidase inhibitors who ingest foods rich in tyramine).[7–9] In addition, poor systolic BP control has been identified as an independent risk factor for the development of hypertensive crisis.[10] Despite improvements in the recognition and treatment of hypertension, a recent study found that severely elevated BP was present in 18% of patients admitted to the emergency department (ED).[11] However, a recent nationwide study demonstrated the frequency of hypertensive emergency is 0.2% among all adult ED visits.[12]

CLINICAL PRESENTATION OF HYPERTENSIVE URGENCY

There are limited data describing the presentation and characteristics of those patients with hypertensive urgency. Mild symptoms may include nausea, epistaxis, fatigue, tinnitus, and psychomotor agitation.[13] Not all patients presenting with a hypertensive urgency will have symptoms.

CLINICAL PRESENTATION OF HYPERTENSIVE EMERGENCY

Similar to hypertensive urgencies, hypertensive emergencies typically occur in those with a history of hypertension. This suggests that hypertensive emergencies are almost entirely preventable.[14,15] Hypertensive emergencies tend to occur in patients with catecholamine-producing adrenal tumors (pheochromocytoma) or renal vascular disease. Additionally, hypertensive emergencies occur more often in African Americans than in Caucasians, among patients who have no primary care physician, and those who are unable adhere to treatment regimens.[14,16]

Symptoms associated with hypertensive emergency are highly variable and reflect the degree of damage to specific organ systems (eg, headache, dizziness, visual changes, and chest discomfort). Rapid, severe BP elevation is not always the hallmark of a hypertensive emergency. The primary sites of damage are the central nervous system, heart, kidneys, and eyes. Although hypertensive emergencies are much less common than hypertensive urgencies, without a thorough patient history, it is often difficult to know whether end-organ dysfunction is acute or chronic in nature.

Central Nervous System

Central nervous system abnormalities, especially cerebrovascular accidents, are the most commonly reported complications in hypertensive emergencies. Symptoms may include a severe headache with or without dizziness, nausea, vomiting, and anorexia. Mental confusion with apprehension indicates more severe damage, as does nystagmus, localized weakness, or a positive Babinski sign (ie, upward extension of the great toe and spreading of the smaller toes when moderate pressure is applied along a curve from the sole to the ball of the foot). Central nervous system damage may rapidly progress, resulting in coma or death. If a cerebrovascular accident has occurred, slurred speech or motor paralysis may be present.[14]

Other Complications

Cardiac consequences are the second most common complication of hypertensive emergency reported. Presentations may include heart failure (HF), acute pulmonary edema, acute aortic dissection, and/or an acute coronary syndrome. Ocular symptoms of hypertensive emergency usually are related to changes in visual acuity. Blurred vision or loss of eyesight are often associated with funduscopic findings of hemorrhages, exudates (yellow deposits within the retina as a result of leaks from capillaries and microaneurysms), and occasionally papilledema (edema of the optic nerve). Acute kidney injury can also develop. Markers of renal dysfunction include hematuria, proteinuria, and elevated serum blood urea nitrogen and serum creatinine levels.

OVERVIEW OF TREATMENT

Oral Versus Parenteral Therapy

Hypertensive urgency can be managed by either restarting or intensifying the patient's oral antihypertensive regimen. Practitioners should exercise caution in aggressive treatment of patients with

elevated BP in the absence of target-organ damage.[17] Aggressive dosing of antihypertensives to rapidly lower BP is not without risk and can lead to hypotension and subsequent morbidity. Some have suggested that the term *hypertensive urgency* leads to overly aggressive treatment and should be discarded in favor of a less ominous term such as *markedly elevated BP*.[1,6] In contrast, hypertensive emergencies require immediate hospitalization, generally in an intensive care unit, and the administration of parenteral antihypertensive medications to reduce arterial pressure.[18] Owing to the disturbance of autoregulation of tissue perfusion, continuous infusions of short-acting titratable antihypertensives are preferred to prevent further end-organ damage in the setting of hypertensive emergency. Effective therapy greatly improves the prognosis, reverses symptoms, and arrests the progression of end-organ damage.[19,20] Whether treatment can completely reverse end-organ damage is related to two factors: How soon treatment is initiated and the extent of damage at the initiation of therapy.

There are two fundamental concepts in the management of hypertensive emergencies. First, immediate and intensive therapy is required and takes precedence over time-consuming diagnostic procedures.[21] Second, the medication selection will depend on their onset of action and hemodynamic and metabolic effects meet the needs of the emergent situation. If encephalopathy, acute left ventricular failure, dissecting aortic aneurysm, eclampsia, or other end-organ damage is present, the BP should be lowered promptly with rapid-acting, parenteral antihypertensive medications such as clevidipine, esmolol, enalaprilat, fenoldopam, hydralazine, labetalol, nicardipine, nitroglycerin, or nitroprusside (**Table 16-2**).[1,3,4,22–26] If a slower BP reduction over several hours or days is acceptable, as in the case of a hypertensive urgency, rapid-acting oral therapy using captopril, clonidine, labetalol, or minoxidil may be used (**Table 16-3**).[3,4,26–28] An alternative option is to restart the patient's home medications and/or titrate the doses in a controlled manner so as not to drop the BP too rapidly.[29] **Figure 16-1** provides an overview of the management of a hypertensive crisis. A summary of treatment

recommendations for acutely lowering BP for selected indications is listed in **Table 16-4**.

Table 16-2
Parenteral Medications Commonly Used in the Treatment of Hypertensive Emergencies

Medication (Brand Name)/Class	Dose/Route	Onset of Action	Duration of Action
Clevidipine (Cleviprex®)/calcium channel blocker	Initial: 1–2 mg/hour; double dose at 90-second intervals until approaching goal BP, then increase by less than double every 5–10 minutes to a max of 21 mg/hour	2–4 minutes	10–15 minutes after D/C infusion
Enalaprilat[a] (Vasotec® IV)/ACE inhibitor	0.625–1.25 mg IV every 6 hours	15 minutes (peak, 1–4 hours)	6–12 hours
Esmolol[b] (Brevibloc®)/β-adrenergic blocker	500–1000 µg/kg IV loading dose, then 50–300 µg/kg/min	β-blockade: 2–10 minutes Hemodynamic effects: 10–30 minutes	10–20 minutes
Fenoldopam (Corlopam®)/dopamine-1 agonist	0.01–0.3 µg/kg/min, increase by 0.05–0.1 µg/kg/min every 15 minutes until goal BP achieved up to a max of 1.6 µg/kg/min	10 minutes	60 minutes
Hydralazine[c] (generic)/arterial vasodilator	10–20 mg IV or IM, can repeat every 20 minutes as needed	10–80 minutes	Up to 12 hours
Labetalol[d] (Normodyne®)/α- and β-adrenergic blocker	10–20 mg IV bolus at a rate of 10 mg/min, repeat every 10 minutes with escalating doses of 20, 40, and then 80 mg to a cumulative max of 300 mg or 0.5–2 mg/min IV infusion titrated at a rate of 0.5 mg/min every 15 minutes	Within 5 minutes Peak effect: 5–15 minutes	3–6 hours
Nicardipine[e] (Cardene® IV)/calcium channel blocker	Initiate at 5 mg/hour IV increased by 2.5 mg/hour every 5–15 minutes to desired BP or a max of 15 mg/hour, may decrease to 3 mg/hour after response achieved although not required	2–10 minutes (max, 8–12 hours)	40–60 minutes after D/C infusion
Nitroglycerin[f] (Tridil®, Nitro-Bid® IV, Nitro-Stat® IV)/venous vasodilator	Initiate at 5–10 µg/min IV infusion increased by 5 µg/min every 3–5 minutes to 20 µg/min then may increase by 10–20 µg/min every 3–5 minutes up to a max of 200 mg/min.	Immediate	3–5 minutes after D/C infusion
Nitroprusside[g] (Nipride®, Nitropress®)/arterial and venous vasodilator	Initiate at 0.1–0.3 µg/kg/min IV infusion increased by 0.2 µg/kg/min every 10–20 minutes to a max of 10 µg/kg/min. Doses >3 µg/kg/min are generally not recommended.	<2 minutes	1–10 minutes after D/C infusion

Medication	Major side effects (all can cause hypotension)	Avoid or use cautiously in patients with these conditions.
Clevidipine	Atrial fibrillation, nausea, vomiting, headache, acute renal failure, reflex tachycardia, and MI	Allergy to soybeans, soy products, eggs or egg products, severe aortic stenosis, defective lipid metabolism (eg, pathologic hyperlipidemia, lipid nephrosis, or acute pancreatitis), and HF
Enalaprilat	Hyperkalemia, acute kidney injury in those who are volume depleted	Hyperkalemia, bilateral renal artery stenosis, and pregnancy (teratogenic)
Esmolol	Nausea, thrombophlebitis, and painful extravasation	Asthma, bradycardia, decompensated HF, and advanced heart block
Fenoldopam	Tachycardia, headache, nausea, and flushing	Glaucoma
Hydralazine	Tachycardia, headache, and angina	Angina pectoris, MI, and aortic dissection

Labetalol	Abdominal pain, nausea, vomiting, and diarrhea	Asthma, bradycardia, and decompensated HF
Nicardipine	Headache, flushing, nausea, vomiting, dizziness, and tachycardia; local thrombophlebitis rotate peripheral infusion site every 12 hours	Angina pectoris, advanced aortic stenosis, decompensated HF, and increased intracranial pressure
Nitroglycerin	Methemoglobinemia, headache, tachycardia, nausea, vomiting, flushing, and tolerance with prolonged use	Pericardial tamponade, constrictive pericarditis, or increased intracranial pressure
Nitroprusside	Nausea, vomiting, diaphoresis, weakness, thiocyanate toxicity,[h] cyanide toxicity (rare),[i] chest pain, nausea, vomiting, dizziness, headache, nasal congestion, and arrhythmia	Renal failure (thiocyanate accumulation), hepatic impairment (cyanide toxicity), pregnancy, increased intracranial pressure, and acute coronary syndrome

ACE, angiotensin-converting enzyme; BP, blood pressure; D/C, discontinued; HF, heart failure; IM, intramuscular; IV, intravenous; MI, myocardial infarction.

[a]Not approved by the U.S. Food and Drug Administration for treatment of acute hypertension.

[b]Approved for intraoperative and postoperative treatment of hypertension.

[c]Parenteral hydralazine is an intermediate treatment between oral agents and more aggressive therapies such as nitroprusside. It can be given IV or intramuscularly, but there is no appreciable difference in onset of action (20–40 minutes) between the two routes. This slow onset minimizes hypotension.

[d]Labetalol is contraindicated in acute decompensated heart failure because of its β-blocking properties. Infusions start at 2 mg/min and are titrated until a satisfactory response or a cumulative dose of 300 mg is achieved.

[e]Indicated for short-term treatment of hypertension when the oral route is not feasible or desirable.

[f]Requires special delivery system owing to drug binding to polyvinyl chloride tubing. Also see Chapter 12, Chronic Stable Angina, and Chapter 13, Acute Coronary Syndrome, for further information regarding nitroglycerin.

[g]The container should be wrapped with metal foil to prevent light-induced decompensation once reconstituted; the product will be a red-brown solution. Under these conditions, the solution is stable for 4 to 24 hours. A rising BP may indicate a loss of potency. A change in color to yellow does not indicate effectiveness. The appearance of a dark brown, green, or blue color indicates loss in activity. When changing to a new bag, the administration rate may require adjustment.

[h]Thiocyanate levels rise gradually in proportion to the dose and duration of administration. The half-life of thiocyanate is 2.7 days with normal renal function and *9* days in patients with renal failure. Toxicity occurs after 7 to 14 days in patients with normal renal function and after 3 to 6 days in renal failure patients. Thiocyanate serum levels should be measured after 3 to 4 days of therapy, and the drug should be discontinued if levels exceed 10 to 12 mg/dL. Thiocyanate toxicity causes a neurotoxic syndrome of toxic psychosis, hyperreflexia, confusion, weakness, tinnitus, seizures, and coma.

[i]Signs of cyanide toxicity include lactic acidosis, hypoxemia, tachycardia, altered consciousness, seizures, and the smell of almonds on the breath. Concurrent administration of sodium thiosulfate or hydroxocobalamin may reduce the risk of cyanide toxicity in high-risk patients.

Table 16-3
Oral Medications Commonly Used in the Treatment of Hypertensive Urgencies

Medication[a] (Brand Name)	Dose/Route	Onset of Action	Duration of Action	Major Side Effects[a]	Avoid or Use Cautiously in Patients With These Conditions
Captopril[b] (Capoten®) 12.5-, 25-, 50-, 100-mg tablets ACE inhibitor	6.5–50 mg PO	15 minutes	4–6 hours	Hyperkalemia, angioedema, increased SCr if volume depletion, rash, pruritus, and loss of taste	Renal artery stenosis, hyperkalemia, volume depletion, acute kidney injury, and pregnancy
Clonidine (Catapres®) 0.1-, 0.2-, 0.3-mg tablets Central α_2-agonist	0.1–0.2 mg PO initially, then 0.1 mg/hour up to 0.8 mg total	0.5–2 hours	6–8 hours	Sedation, dry mouth, bradycardia, and constipation	Altered mental status and severe carotid artery stenosis
Labetalol (Normodyne®, Trandate®) 100-, 200-, 300-mg tablets α-and β-adrenergic blocker	200–400 mg PO repeated every 2–3 hours	30 minutes–2 hours	4 hours	Orthostatic hypotension, nausea, and vomiting	HF, asthma, bradycardia, and advanced heart block
Minoxidil (Loniten®) 2.5-, 10-mg tablets Arterial and venous vasodilator	5–20 mg PO	30–60 minutes; maximum response in 2–4 hours	12–16 hours	Tachycardia and fluid retention	Angina and HF

ACE, angiotensin-converting enzyme; HF, heart failure; PO, orally; SCr, serum creatinine.

[a]All may cause hypotension, dizziness, and flushing.

[b]Other oral ACE inhibitors are too slow in onset to be useful but should be used for maintenance therapy to improve adherence as captopril requires multiple daily doses.

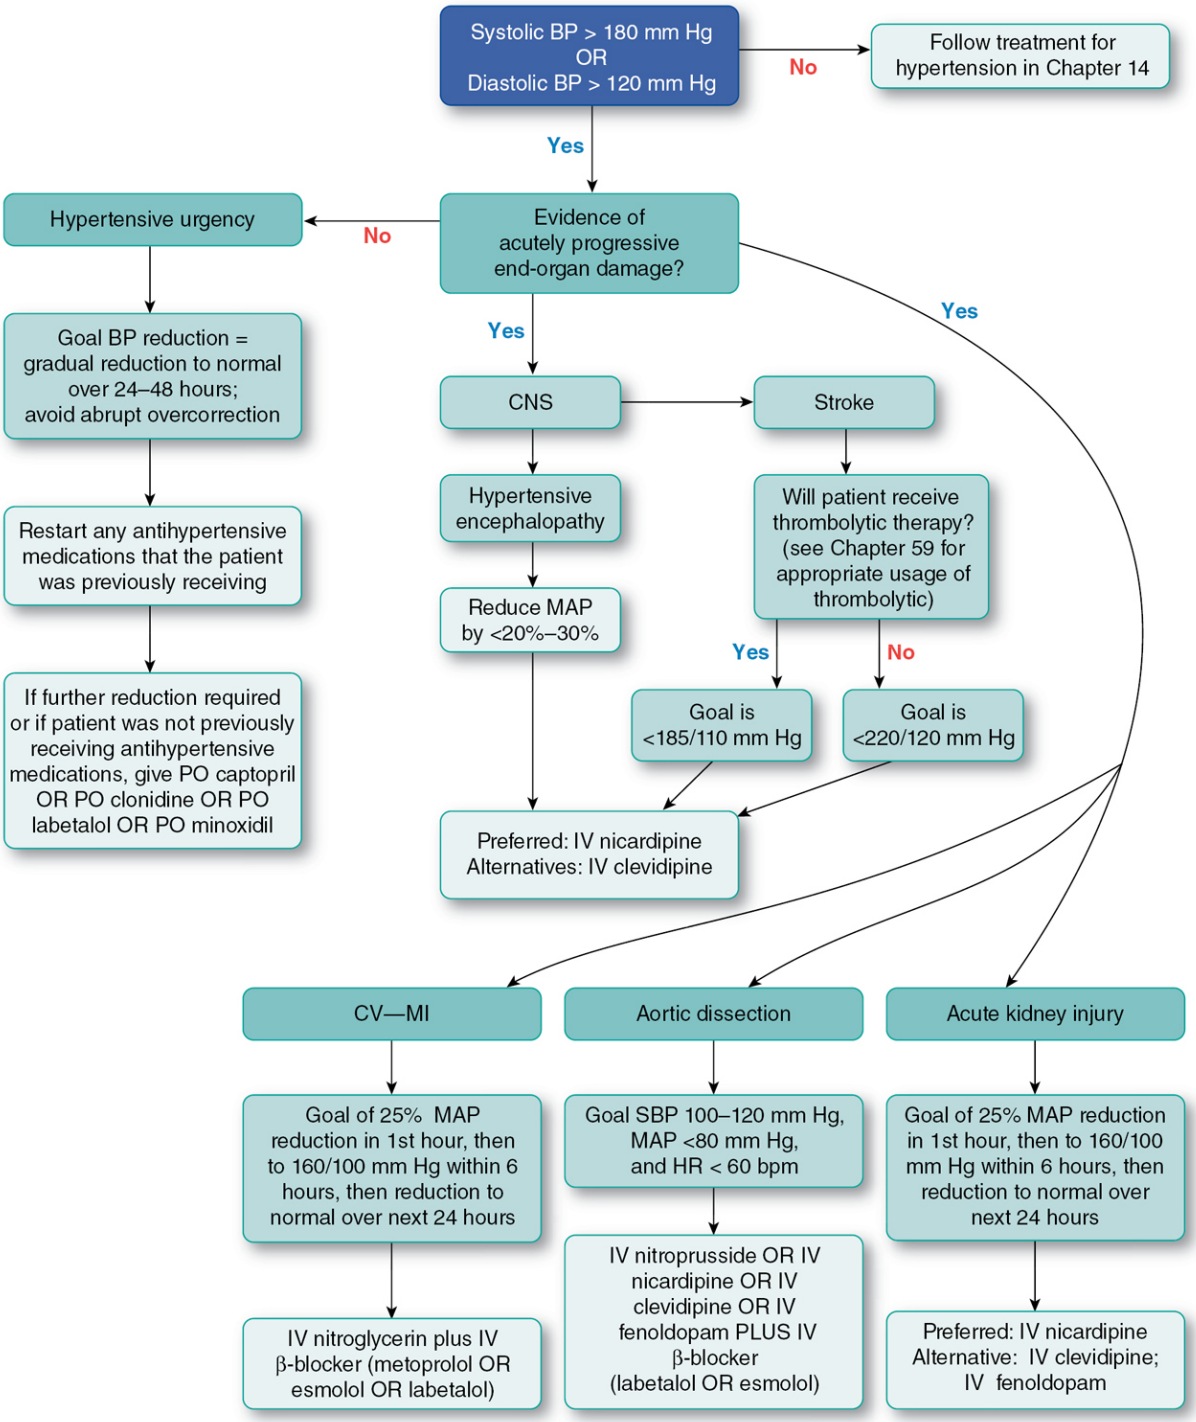

Figure 16-1 Overview of management for a hypertensive crisis. BP, blood pressure; CNS, central nervous system; CV, cardiovascular; HR, heartrate; IV, intravenous; MAP, mean arterial pressure; MI, myocardial infarction; SBP, systolic blood pressure.

Table 16-4
Treatment Recommendations for Hypertensive Emergency

Clinical Presentation	Recommendation	Rationale
Acute aortic dissection	Nitroprusside, nicardipine, clevidipine, or fenoldopam plus esmolol or IV metoprolol or labetalol; trimethaphan. Avoid inotropic therapy.	Vasodilator will decrease pulsatile stress in aortic vessel to prevent further dissection expansion. β-Blockers will prevent vasodilator-induced reflex tachycardia.
Angina and myocardial infarction	Nitroglycerin plus esmolol or metoprolol or labetalol. Avoid nitroprusside.	Coronary vasodilation, decreased cardiac output, myocardial workload, and oxygen demand. Nitroprusside may cause coronary steal.
Acute pulmonary edema and left ventricular failure	Nitroprusside or nitroglycerin and a loop diuretic. Alternative: enalaprilat. Avoid nondihydropyridines and β-blockers.	Promotion of diuresis with venous dilatation to decrease preload. Nitroprusside and enalaprilat decrease afterload. Nicardipine may increase stroke volume.
Acute kidney injury	Nicardipine, clevidipine, or fenoldopam. Avoid nitroprusside or enalaprilat.	Peripheral vasodilation without affecting renal clearance
Cocaine use	Nicardipine, clevidipine, fenoldopam, verapamil, or nitroglycerin. Alternative: labetalol. Avoid β-selective blockers.	Vasodilation effects without potential unopposed α-adrenergic receptor stimulation. CCBs controle cocaine-induced vasospasm.

Clinical Presentation	Recommendation	Rationale
Pheochromocytoma	Nicardipine, clevidipine, fenoldopam, or verapamil. Alternatives: labetalol. Avoid β-selective blockers.	Vasodilation effects without potential unopposed α-adrenergic receptor stimulation
Eclampsia or preeclampsia	Hydralazine, labetalol, or nicardipine	Requires rapid BP lowering. ACE inhibitors, ARBs, and nitroprusside are contraindicated.
Hypertensive encephalopathy, intracranial hemorrhage, subarachnoid hemorrhage, ischemic stroke, and thrombotic stroke	Nicardipine, clevidipine, or labetalol. Avoid nitroprusside, nitroglycerin, enalaprilat, and hydralazine.	Vasodilation effects without compromised CBF induced by nitroprusside and nitroglycerin; Enalaprilat and hydralazine may lead to unpredictable BP changes when carefully controlled BP management is required.

ACE, angiotensin-converting enzyme; ARB, angiotensin-receptor blocker; BP, blood pressure; CBF, cerebral blood flow; CCB, calcium channel blocker; IV, intravenous.

Goals of Therapy

The rate of BP lowering must be individualized, depending on whether the patient presents with hypertensive urgency or emergency. Also, ischemic damage to the heart and brain can be provoked by a precipitous fall in BP.[28–33] As treatment is initiated, clinicians should recognize that the elderly and patients with severely defective autoregulatory mechanisms are at high risk for developing hypotensive complications. The latter group includes those with autonomic dysfunction or fixed sclerotic stenosis of cerebral or neck arteries.[34] In addition, patients who have chronically elevated BP are less likely to tolerate abrupt reductions in their BP, and the amount of reduction appropriate for those patients is somewhat less than for those whose BP is acutely elevated.

For hypertensive emergencies complicated by aortic dissection, pheochromocytoma crisis, severe preeclampsia, or eclampsia, it is recommended that the SBP is reduced to <140 mm Hg during the first hour and to 100 to 120 mm Hg in aortic dissection (Case 16-6).[1] For hypertensive emergencies with the presence of other end-organ damage, mean arterial pressure should be reduced initially by no more than 25% (within minutes to 1 hour); then if stable, this should be followed by further reduction toward a goal of 160/100–110 mm Hg within 2 to 6 hours and gradual reduction to normal during the next 24 to 48 hours.[4] A DBP of 100 to 110 mm Hg is an appropriate initial therapeutic goal.[1]

Another exception to this rule applies to patients with acute cerebrovascular accidents. Cerebral autoregulation is disrupted in this setting, and the use of antihypertensives may cause a reduction in cerebral blood flow and increased morbidity.[35] Current guidelines recommend lowering BP after acute ischemic stroke if the systolic BP is >220 mm Hg or the DBP is >120 mm Hg by 15% within 24 hours in patients ineligible for thrombolytic therapy; a lower BP goal can be achieved, if medically necessary, to manage a condition such as an MI or aortic dissection. The SBP should be lowered to <185 mm Hg and DBP to <110 mm Hg in candidates for thrombolytics or mechanical thrombectomy.[36] The systolic BP should be maintained at <180 mm Hg and the DBP at <105 mm Hg for the first 24 hours after thrombolytic therapy. A lower BP in patients undergoing thrombolytic therapy reduces the risk of intracerebral bleeding.[36] Additionally, in those with hypertensive encephalopathy, cerebral hypoperfusion may occur if the mean BP is reduced by more than 40%.[37] Thus, in the presence of hypertensive encephalopathy, it is suggested that within the first hour of treatment, the mean arterial pressure be lowered by no more than 20% or to a DBP of 100 mm Hg, whichever is greater.[37,38]

HYPERTENSIVE URGENCIES

Patient Assessment

CASE 16-1

QUESTION 1: M.M. is a 60-year-old male with a long history of HF with a preserved ejection fraction (HFpEF), poorly controlled hypertension believed to be caused by nonadherence, and a history of MI. He was referred from a community health center this morning for a thorough evaluation of his elevated BP. He has not taken his enalapril, clonidine, or carvedilol for the past 7 days. M.M. is completely asymptomatic. Physical examination reveals a BP of 198/130 mm Hg and a pulse of 92 beats/min. Funduscopic examination is pertinent for mild arteriolar narrowing, without hemorrhages or exudates. The discs are flat. His lungs are clear, and the cardiac examination is unremarkable. The electrocardiogram indicates normal sinus rhythm at a rate of 90 beats/min. The chest radiograph is interpreted as mild cardiomegaly. Serum electrolytes, blood urea nitrogen, and serum creatinine are within normal limits. A urinalysis is significant for 2+ proteinuria.

How quickly should his BP be lowered, and what therapeutic options are available?

The absolute magnitude of BP elevation does not in itself constitute a medical emergency requiring an acute reduction in BP. There is no evidence of encephalopathy, cardiac decompensation, chest pain, or rapid change in renal function. Therefore, no evidence exists to indicate a rapid deterioration in the function of target organs. One would classify M.M.'s case as a hypertensive urgency.

As is often the case, M.M.'s lack of BP control is related to medication nonadherence. M.M.'s clinical presentation requires that his BP be lowered during the next 24 to 48 hours while being careful not to induce hypotension. At this time, no specific evidence exists supporting a BP reduction goal, although a goal of reducing the mean arterial pressure by 20% to 25% over several days may be reasonable. Aggressive reductions with intravenous (IV) antihypertensives and even some oral agents are associated with the development of syncope, stroke, and MI; thus, this should be avoided. A variety of rapid-acting oral agents such as clonidine, captopril, labetalol, or minoxidil can be used for this purpose. Restarting his previously prescribed medications in a controlled

manner, so as not to drop his BP too rapidly, may also be a reasonable option for treatment. Later, he can be converted to a regimen designed to enhance adherence by selecting medications with once-daily dosing. For example, lisinopril or another long-acting angiotensin-converting enzyme (ACE) inhibitor would be preferred for maintenance instead of the enalapril previously prescribed owing to the frequency of doses required. One should also determine and address barriers to medication adherence with the patient including the cost of therapy, lack of understanding of the benefits of therapy, misconceptions of the side effect profiles, and so forth. Timely follow-up within 1 week after treatment of hypertensive urgency is of paramount importance for the appropriate management of these patients.

Oral Drug Therapy

RAPIDLY ACTING CALCIUM CHANNEL BLOCKERS

Case 16-1, Question 2: M.M.'s physician has ordered immediate-release nifedipine 10 mg to be given sublingually. Is this appropriate therapy to treat his hypertensive urgency?

Captopril, clonidine, labetalol, and minoxidil have all been used to lower BP acutely. These oral agents take several hours to adequately lower pressure and are therefore useful in treating hypertensive urgencies but not emergencies. Oral-acting ACE inhibitors, other than captopril, are not useful for acutely lowering BP because of a slower onset of action.

The immediate-release calcium channel blockers, including diltiazem, verapamil, and nicardipine, can rapidly lower BP; however, the most extensive experience is with nifedipine. Nifedipine, when given orally or by the "bite and swallow" method, was previously recommended as a rapid-acting alternative to parenteral therapy in the acute management of hypertension. However, its use has been associated with life-threatening adverse events related to ischemia,

MI, and stroke.[29–33] The cavalier use of immediate-release nifedipine to acutely lower BP is potentially dangerous and should be avoided.[39,40] M.M.'s BP can be managed safely using other oral medications.

CLONIDINE

Case 16-1, Question 3: A decision is made not to use nifedipine, but rather to give M.M. oral clonidine. What is an appropriate starting and maintenance dose?

Clonidine is considered a generally safe, and effective first-line therapy for hypertensive urgency. It is a centrally acting, α_2-adrenergic agonist that inhibits sympathetic outflow from the central nervous system. BP can be lowered gradually over several hours using oral clonidine. Traditional dosing regimens have included an initial oral loading dose (0.1–0.2 mg) followed by repeated doses of 0.1 mg/hour until the desired response is achieved or until a cumulative dose of 0.8 mg is reached.[41] Some authors, however, have cautioned against the use of sequential loading doses, citing lack of benefit over placebo and the potential for unpredictable adverse effects, particularly abrupt occurrences of significant hypotension.[42] If loading doses are to be used, it is especially important to reduce doses in patients with volume depletion, those who have recently used other antihypertensive drugs, and the elderly.[1,25,43]

The acute response to oral clonidine loading is not predictive of the daily dose required to maintain BP control. Maintenance oral therapy with clonidine is somewhat empiric; however, total daily doses should be spread between two and three times daily dosing owing to the drug's short half-life.

Adverse effects and precautions

Case 16-1, Question 4: What are the adverse effects and precautions that should be considered before recommending the use of clonidine?

Oral clonidine is generally well tolerated. Adverse effects include orthostatic hypotension, bradycardia, sedation, dry mouth, and dizziness. Clonidine can decrease cerebral blood flow by up to 28%; it should not be used in patients with severe cerebrovascular disease.[44] Clonidine also should be avoided in patients with HF, bradycardia, sick sinus syndrome, or cardiac conduction defects[25] as well as in patients at risk of medication nonadherence because of potential rebound hypertension following abrupt discontinuation.[45,46]

OTHER ORAL DRUGS

Captopril

Case 16-1, Question 5: M.M. has a history of HFpEF and normal renal function. Based on these findings, would captopril be a reasonable choice for initial treatment? What would be an appropriate initial dosing regimen? What if he had acute kidney injury?

Captopril has been used both orally and sublingually to acutely lower BP.[47,48] Although sublingual captopril has been used because of its rapid onset of action, the overall BP reduction at 60 minutes is similar between sublingual and oral administration.[49] Captopril decreases both afterload and preload and lowers total peripheral vascular resistance.[25] For this reason, captopril and other ACE inhibitors are often considered the drugs of choice in patients with HF with reduced ejection fraction as they have been shown to reduce mortality in this patient population (see Chapter 14, Heart Failure, for further discussion). M.M. has HFpEF; the evidence of using ACE inhibitors in reducing mortality in this patient population is not strong. However, given that M.M. appeared to be well controlled on his enalapril therapy before abruptly stopping his medications, it is reasonable to restart a rapid-acting ACE inhibitor and reinforce medication adherence issues. Additionally, in patients with diabetic

or nondiabetic proteinuria, ACE inhibitors can reduce the level of urinary protein excretion and progression of Chronic Kidney Disease (CKD), making these agents an optimal first-line treatment option for M.M.[1]

After oral administration, the onset of action of captopril occurs within minutes and peaks 30 to 90 minutes later.[50] Clinically, it reduces BP within 10 to 15 minutes, with effects persisting for 2 to 6 hours. Sublingual captopril is as effective as nifedipine but without reflex tachycardia in acutely reducing mean arterial pressure in both urgent and emergent conditions.[48–52]

Despite these beneficial effects, captopril, as well as long-acting ACE inhibitors, must be used with caution in patients with renal insufficiency or volume depletion. In most cases, an elevated blood urea nitrogen or serum creatinine will provide a clue to the existence of these conditions; however, captopril can also induce renal failure in patients with bilateral renal artery stenosis or renal artery stenosis in a solitary kidney. Such conditions may not be easy to detect in the context of an acute hypertensive emergency. Therefore, in patients in whom these conditions can be excluded, captopril can be considered for initial therapy. First-dose hypotension is a common limiting factor with captopril use. This complication is most likely to occur in the elderly and in patients with high renin levels, such as those who are volume depleted or those receiving diuretics. Under these circumstances, initial doses should not exceed 12.5 mg, with repeat doses an hour or more later if necessary. Therefore, captopril would be a reasonable choice as initial therapy in M.M., which can later be replaced by a longer-acting ACE inhibitor.

Minoxidil and labetalol

Case 16-1, Question 6: What other oral agents can be considered in the treatment of hypertensive urgency?

Minoxidil, a potent oral vasodilator, has been used successfully in the treatment of hypertensive urgencies.[53,54] An oral loading dose of

10 to 20 mg produces a maximal BP response in 2 to 4 hours and can be followed by a dose of 5 to 20 mg every 4 hours if necessary. Unfortunately, its onset of action is slower than that of clonidine or captopril. Another complicating factor is that β-blockers and loop diuretics generally must be used concomitantly to counteract minoxidil-induced reflex tachycardia and fluid retention.[54] Because of this, minoxidil should only be prescribed by those who have experience with prescribing this agent and managing these adverse effects. These adverse effects make this agent a less preferred choice in M.M. because of his history of HF. Minoxidil should be used only in patients presenting with hypertensive urgency who are not responding to other antihypertensive therapies or who have previously been taking this agent.

Oral labetalol, a combined α- and β-receptor antagonist, is an alternative to oral clonidine or captopril for the treatment of severe hypertension, but the most appropriate dosing regimen remains to be determined.[55–58] Initial doses of 100 to 300 mg may provide a sustained response for up to 4 hours.[56] Labetalol (200 mg given at hourly intervals to a maximum dose of 1200 mg) was comparable to oral clonidine in reducing mean arterial pressure.[58] An alternative regimen using 300 mg initially followed by 100 mg at 2-hour intervals to a maximum of 500 mg was also successful in acutely lowering BP.[57] Other literature has reported that a single loading dose of 200 to 400 mg does not appear to be effective in achieving an adequate BP response.[59] Because labetalol can cause profound orthostatic hypotension, patients should remain in the supine position and should be assessed for orthostasis before ambulation. In addition, owing to its β_1- and β_2-receptor antagonism, labetalol should be avoided in patients with asthma or obstructive pulmonary disease, bradycardia, or advanced heart block.

HYPERTENSIVE EMERGENCIES

Patient Assessment

CASE 16-2

Question 1: M.R., a 55-year-old male, presents to the ED with a 3-day history of progressively increasing shortness of breath. During the past 2 days, he experienced a severe headache unrelieved by ibuprofen, as well as chest pressure, which worsened with exertion, anorexia, and nausea. His medical history includes hypertension, asthma, and chronic stable angina. His medications include albuterol via metered-dose inhaler, isosorbide dinitrate, felodipine, and lisinopril; however, he discontinued these medications on his own 3 weeks ago.

Physical examination reveals an anxious-appearing male who is alert, oriented, and in moderate respiratory distress. His vital signs include a heart rate of 125 beats/min, respiratory rate of 36 breaths/min, BP of 220/145 mm Hg without orthostasis, and a normal body temperature. Funduscopic examination shows arteriolar narrowing and arteriovenous nicking without hemorrhages, exudates, or papilledema. No jugular venous distention is observed, but bilateral carotid bruits are present. Chest examination reveals decreased breath sounds with bilateral rales extending to the tip of the scapula. M.R.'s heart is displaced 2 cm to the left of the midclavicular line with no thrills or heaves. The rhythm is regular with an S_3 and an S_4 gallop; no murmurs are noted. The remainder of M.R.'s examination is within normal limits.

Significant laboratory values include the following:

Sodium, 142 mEq/L
Potassium, 4.9 mEq/L
Chloride, 101 mEq/L
Bicarbonate, 23 mEq/L
Urea nitrogen, 30 mg/dL
Serum creatinine, 1.2 mg/dL
Hematocrit, 38%
Hemoglobin, 13 g/dL
White blood cell count and differential, within normal limits
Troponin—negative × 2

Urinalysis shows 1+ hemoglobin and 1+ protein. Microscopic examination of the urine reveals 5 to 10 red blood cells per high-power field and no casts. Pulse oximetry reveals an oxygen saturation of 88%. An electrocardiogram demonstrates sinus tachycardia and left ventricular hypertrophy but no T wave changes compared to baseline. The chest radiograph shows moderate cardiomegaly and bilateral fluffy pulmonary infiltrates.

What aspects of M.R.'s history and physical examination are characteristic of an emergent need to immediately lower his BP?

Hypertensive crisis occurs most often in males and in individuals between ages 40 and 60 years. Furthermore, many patients who present with hypertensive crisis have a recent history of discontinuing the use of their antihypertensives,[14,16] as is the case with M.R. in Case 16-2 and M.M. in Case 16-1.

Recent-onset severe headache, nausea, and vomiting are consistent with central nervous system signs of severe hypertension, as are the acute onset of angina (substernal chest pain) and acute HF (shortness of breath, increased pulse and respiratory rate, cardiomegaly, S_3, and chest radiographic findings of pulmonary edema). The absence of signs of right-sided HF such as jugular venous distention or hepatomegaly suggests an acute onset of HF caused by hypertension as opposed to a gradual worsening of chronic HF. M.R.'s urinary sediment is relatively unimpressive at this time, especially in light of his history, and his ocular complications are minimal. M.R.'s presentation is considered hypertensive emergency because of the presence of HF symptoms; M.R. should be admitted to the hospital as IV antihypertensive therapy is warranted.

Parenteral Drug Therapy

NITROPRUSSIDE

Case 16-2, Question 2: M.R. is to be started on nitroprusside. Is this an appropriate choice of drug? What alternatives to nitroprusside are available?

M.R.'s arterial pressure should be lowered with parenteral medications, which have a rapid onset of action. Nitroprusside, fenoldopam, and IV nitroglycerin all decrease total peripheral resistance rapidly with minimal effect on myocardial oxygen consumption and heart rate. Of these agents, either nitroprusside or fenoldopam would be preferred in patients with hypertension accompanied by decompensated HF in the absence of MI. Parenteral nitroglycerin is similar to nitroprusside except that it has a

relatively greater effect on venous circulation and less effect on arterioles. It is most useful in patients presenting with angina secondary to coronary insufficiency, ischemic heart disease, MI, or hypertension after coronary bypass surgery (also see Case 16-3, Question 6). In addition, both nitroprusside and IV nitroglycerin may decrease elevated left ventricular diastolic pressures in patients presenting with hypertensive emergency and pulmonary edema. Although nitroglycerin may be used preferentially for someone who is experiencing chest pain in the setting of an MI, this patient is not having an acute coronary syndrome, which is confirmed by negative troponins and electrocardiogram. Before considering nitroprusside, it is important to consider the etiology of the chest pain. As described earlier, the chest discomfort is likely caused by acute-onset HF owing to severe hypertension. Nitroprusside provides an advantage over nitroglycerin because it provides both arterial and venous vasodilation, allowing for further reduction in peripheral resistance and left ventricular diastolic pressures. Nitroglycerin has a relatively greater effect on venous circulation, especially at lower doses.

Fenoldopam and nitroprusside are equally efficacious in acutely lowering BP.[60–63] Both medications have an immediate onset, are easily titratable, have a short duration of action, and are relatively well tolerated.[64–67] Unlike nitroprusside, fenoldopam does not cause cyanide or thiocyanate toxicity. However, fenoldopam is associated with dose-related tachycardia and should be avoided in those with concern for active coronary ischemia.

Therefore, in the absence of any significant renal or liver disease, nitroprusside is the preferred treatment for M.R.

Hemodynamic effects

Nitroprusside has many pharmacologic effects that should improve M.R.'s condition. It dilates both venous and arterial vessels, thereby increasing venous capacitance and decreasing the venous return or preload on the heart (see Chapter 14, Heart Failure). A decrease in the pulmonary capillary wedge pressure and ventricular filling pressure will ultimately improve M.R.'s pulmonary edema. Afterload

is also decreased as a result of arterial dilation. This action increases cardiac output, reduces arterial pressure, and increases tissue perfusion.

Concurrent use of diuretics

Case 16-2, Question 3: Should M.R. be given a diuretic before nitroprusside therapy is begun?

Administration of potent IV diuretics is relatively ineffective in the acute treatment of hypertensive crisis except in patients with concomitant volume overload or HF. Many patients with hypertensive emergencies are vasoconstricted and have normal or reduced plasma volumes; therefore, diuretics have little effect and may actually aggravate renal impairment or cause other adverse effects.[24,68] Furthermore, when diuretics are given acutely in combination with other antihypertensive agents, profound hypotension can occur.

The immediate value of diuretics in acute HF is related more to their hemodynamic effects (venodilation) than to diuresis. Venodilation after IV diuretic administration decreases right-sided cardiac filling pressures, decreases pulmonary artery and wedge pressures, and increases cardiac output before diuresis occurs.[69] The presence of HF, pulmonary edema, and severely elevated BP in M.R. warrants IV administration of a loop diuretic (eg, furosemide [Lasix®] 40 mg, torsemide [Demadex®] 10–20 mg, or bumetanide [Bumex®] 1 mg) in addition to nitroprusside.

Dosing and administration

Case 16-2, Question 4: What dose of nitroprusside should be used initially?

Effective infusion rates range from 0.1 to 10 µg/kg/min.[70,71] For M.R., an infusion of nitroprusside should be initiated at a rate of 0.1

μg/kg/min. The dose should be increased slowly by 0.2 μg/kg/min every 10 to 20 minutes until the desired pressure is achieved. Although a maximum infusion rate of 10 μg/kg/min has been recommended, this rate should not be continued for more than 10 minutes. If adequate BP control has not been achieved within this time frame, nitroprusside should be discontinued and alternative therapy initiated.[4] The dosage must be individualized according to patient response using continuous intraarterial BP recording and observing for signs or symptoms of toxicity.

Nitroprusside decomposes on exposure to light, so the solution should be shielded with an opaque sleeve. It is not necessary to protect the tubing from light. Reconstituted solutions are stable for 24 hours at room temperature. A change in the solution's color from light brown to dark brown, green, orange, or blue indicates a loss in activity. The solution should be discarded if this change occurs.

Therapeutic end point

Case 16-2, Question 5: A nitroprusside infusion is started. What is the goal of therapy?

For most patients, BP should be reduced by no more than 25% within the first hour, then if stable, therapy can be titrated to achieve a goal BP of 160/100 mm Hg during the next 2 to 6 hours. BPs can then be reduced to 140/80 mm Hg levels within 24 to 48 hours. However, because M.R. has a cerebral occlusive disease (carotid bruits), excessive reduction of his BP should be avoided to minimize the risk of decreased cerebral blood flow causing stroke or other neurologic complications.

Normal cerebral blood flow remains relatively constant over a wide range of systemic BP measurements through autoregulatory mechanisms.[43,72] The autoregulatory effects can prevent large alterations in cerebral blood flow from either slow or rapid changes in systemic arterial pressures. In addition, the arterial BP required to maintain cerebral perfusion is higher in patients with hypertension

than in normotensive individuals. If M.R.'s BP is reduced excessively, cerebral blood flow may decrease sharply. Therefore, a DBP of 100 to 105 mm Hg would be a reasonable initial therapeutic goal for him in the first 6 hours. If hypotension occurs, nitroprusside should be discontinued, and M.R. should be placed in the Trendelenburg position, in which the head is kept lower than the trunk.

Cyanide toxicity

Case 16-2, Question 6: M.R. is being treated with nitroprusside. However, during the last 24 hours, dose titration to 7 µg/kg/min has been necessary to control his BP. His tachycardia, chest discomfort, and dyspnea have resolved. Is he at risk of developing cyanide toxicity? What indices of toxicity should be monitored? Are there agents available to prevent toxicity?

A major concern when using sodium nitroprusside is toxicity secondary to the accumulation of its metabolic by-products, cyanide, and thiocyanate. Sodium nitroprusside decomposes within a few minutes after IV infusion. Free cyanide, which represents 44% of nitroprusside by weight, is released into the bloodstream, producing prussic acid (hydrogen cyanide), which is responsible for acute toxicity.[73] The amount of hydrogen cyanide released is dose related.[74] Endogenous detoxification of cyanide occurs through a mitochondrial rhodanese system, which, in the presence of a sulfur donor such as thiosulfate, converts cyanide to thiocyanate.[73] Theoretically, cyanide can be expected to accumulate in the body when the rate of the sodium nitroprusside infusion exceeds 2 µg/kg/min for a prolonged period, or when doses exceed 4 µg/kg/min for as short as 2 to 3 hours. The presence of hepatic or renal impairment may also predispose the patient to cyanide toxicity.[75,76]

Symptomatic cyanide toxicity occurs infrequently; however, several deaths have been reported after the use of sodium nitroprusside.[77] Cyanide toxicity occurs most commonly when large doses (total dose 1.5 mg/kg) of nitroprusside are administered rapidly to patients undergoing a surgical procedure that requires induction of hypotension. However, cyanide toxicity and mortality

associated with nitroprusside exceed 1000 and 3000 cases per year, respectively, according to two sources.[77,78]

Although concurrent sodium thiosulfate administration has been recommended in high-risk patients, no clinical data are available to indicate that it reduces overall mortality.[79] Furthermore, this intervention may result in the accumulation of thiocyanate, particularly if sodium thiosulfate is given at high infusion rates or to patients with renal insufficiency. Hydroxocobalamin has also been used to reduce the risk of cyanide toxicity secondary to nitroprusside infusions, but its use is limited because of poor availability and cost considerations.[76] With the availability of safer alternatives (eg, fenoldopam, IV labetalol, IV nicardipine, and IV clevidipine) for use in high-risk patients, the use of hydroxocobalamin or thiosulfate is rarely required.

Cyanide toxicity can be detected early by monitoring M.R.'s metabolic status. Lactic acidosis is an early indicator of toxicity because the progressive inactivation of cytochrome oxidase by cyanide results in increased anaerobic glycolysis.[80,81] A low plasma bicarbonate concentration and low pH, accompanied by an increase in the blood lactate or lactate-to-pyruvate ratio could indicate cyanide toxicity.[81] Additional signs of cyanide intoxication include tachycardia, altered consciousness, coma, convulsions, and the occasional smell of almonds on the breath.[74,81] Measuring serum thiocyanate levels is of no value in detecting the onset of cyanide toxicity. If toxicity develops, the infusion should be stopped and appropriate therapy for cyanide intoxication instituted. The need for such a high-dose infusion of nitroprusside to maintain M.R.'s pressure may increase his risk for cyanide toxicity, warranting close monitoring of his acid–base balance or converting to alternative therapy.

Thiocyanate toxicity

Case 16-2, Question 7: What are the differences between cyanide toxicity and thiocyanate toxicity. What is M.R.'s risk for thiocyanate toxicity if he is continued on a dose of 7 µg/kg/min? Is monitoring of serum thiocyanate concentrations necessary?

Sodium nitroprusside is more likely to produce thiocyanate toxicity. Although this complication is also rare, patients with renal impairment who receive infusions beyond 72 hours are particularly susceptible. Conversion of cyanide to thiocyanate, via sulfation by the liver, proceeds relatively slowly. The half-life of thiocyanate is 2.7 days with normal renal function and up to 9 days in patients with renal failure.[82] When sodium nitroprusside is infused for several days at moderate dosages (2–5 µg/kg/min), toxic levels of thiocyanate can occur within 7 to 14 days in patients with normal renal function and 3 to 6 days in patients with severe renal disease.[73]

Thiocyanate causes a neurotoxic syndrome manifested by psychosis, hyperreflexia, confusion, weakness, tinnitus, seizures, and coma.[75,82] Prolonged exposure to thiocyanate can suppress thyroid function through inhibition of iodine uptake and binding by the thyroid gland.[82] Measurement of blood levels of thiocyanate is only recommended in patients with renal disease or when the duration of the nitroprusside infusion exceeds 3 or 4 days. Nitroprusside should be discontinued if serum thiocyanate levels exceed 10 to 12 mg/dL.[83,84] Life-threatening toxicity is of concern when blood thiocyanate levels exceed 20 mg/dL. In emergency cases, thiocyanate can be readily removed by hemodialysis.[82]

For M.R., the potential for thiocyanate toxicity is low because his renal function is normal and the infusion duration currently has been relatively short. Therefore, measurement of thiocyanate levels is not indicated at this time.

Other side effects associated with nitroprusside therapy include nausea, vomiting, diaphoresis, nasal stuffiness, muscular twitching, dizziness, and weakness. These effects are usually acute and associated with rapid infusion rates.

Case 16-2, Question 8: M.R.'s serum chemistries and arterial blood gas values indicate metabolic acidosis. Should the nitroprusside infusion be continued at 7 µg/kg/min? What alternatives are available?

Although the duration of M.R.'s nitroprusside therapy has been short, tolerance to the antihypertensive effect requires the use of a high-dose infusion to maintain BP control. Thus, acidosis may represent toxicity as a result of cyanide accumulation. The nitroprusside infusion should be discontinued at this time, and another rapidly acting, easily titratable parenteral antihypertensive such as fenoldopam or IV nitroglycerin should be initiated.

FENOLDOPAM

CASE 16-2, QUESTION 9: What are the advantages and disadvantages of fenoldopam compared with sodium nitroprusside?

Fenoldopam is a parenteral, rapidly acting, peripheral dopamine-1 agonist used to manage hypertensive crisis when a rapid reduction in BP is required.[85–88] Stimulation of the dopamine-1 receptors vasodilates coronary, renal, mesenteric, and peripheral arteries.[89,90] Fenoldopam has been used to control perioperative hypertension in patients undergoing cardiac bypass surgery as it had been thought to improve renal blood flow and maintain glomerular filtration.[91] This has been refuted after it was demonstrated that low-dose fenoldopam does not reduce the risk of renal replacement therapy or 30-day mortality.[66,90,92]

Fenoldopam is as effective as sodium nitroprusside for the treatment of hypertensive emergencies and does not cause either cyanide or thiocyanate toxicity.[61–63] Fenoldopam can be considered as an alternative to nitroprusside in patients who are at high risk for cyanide or thiocyanate toxicity, although its use has decreased considerably owing to its significantly higher cost.

Clearance of fenoldopam is not altered by renal or liver disease. Like nitroprusside, fenoldopam also has a short duration of action, with an elimination half-life of ~5 minutes, thus allowing for easy titration.[87,93] BP and heart rate should be monitored frequently to avoid hypotension and dose-related reflex tachycardia. Flushing and headache may occur. Serum potassium should be monitored and

repleted as necessary. Fenoldopam should be used cautiously in patients with glaucoma or intraocular hypertension owing to a dose-dependent increase in intraocular pressure.[94,95]

Case 16-2, Question 10: Which antihypertensive agents should be avoided in M.R.? Why?

Labetalol, a potent, rapidly acting antihypertensive with both α- and β-blocking activity, is very effective in the treatment of hypertensive emergencies,[95–102] but it should not be used in M.R. Hemodynamically, labetalol reduces peripheral vascular resistance (afterload), BP, and heart rate, with almost no change in the resting cardiac output or stroke volume.[103]

M.R. was experiencing chest pain and had tachycardia on admission; these signs and symptoms are most likely caused by his severely elevated BP and the presence of acute left ventricular failure. Although labetalol may have alleviated M.R.'s angina, the negative inotropic action could acutely compromise his left ventricular dysfunction, an effect that outweighs the potential benefit of afterload reduction. In addition, although labetalol is one of the safest β-blocking drugs when used in patients with asthma,[104] β-blocker therapy should be avoided as initial treatment in patients with asthma. Labetalol should be used only if alternative methods of reducing M.R.'s BP fail.

LABETALOL

CASE 16-3

Question 1: C.M., a 52-year-old male, is admitted to the hospital with a 3-day history of increasing exertional substernal chest pain (without shortness of breath), diaphoresis, nausea, and vomiting. His history is significant for poorly controlled hypertension, glaucoma, and angina pectoris. Prior medications include dorzolamide ophthalmic drops, atenolol, hydrochlorothiazide, and oral nitrates. Physical examination reveals an anxious male who is alert and oriented. He has a BP of 210/146 mm Hg without orthostasis and a regular pulse of 115 beats/min. Bilateral hemorrhages and exudates are present on

funduscopic examination. The lungs are clear, and the point of maximal impulse is displaced. There are no murmurs or gallops. Examination of the abdomen is unremarkable, and there is no peripheral edema. The neurologic examination is normal.

Significant laboratory values include the following:

Urea nitrogen, 49 mg/dL
Serum creatinine, 2.8 mg/dL

Serum creatinine was previously noted to be 1.2 mg/dL. Urinalysis shows proteinuria and hematuria. The electrocardiogram demonstrates sinus tachycardia with left-axis deviation, left ventricular hypertrophy, and nonspecific ST-T wave changes. The chest radiograph reveals mild cardiomegaly.

C.M. is given nitroglycerin sublingually, and 1 inch of nitroglycerin ointment is applied topically. He is started on IV labetalol.

Is this choice of treatment reasonable, considering C.M.'s angina and acute kidney injury?

The presence of chest pain, retinopathy, new-onset renal disease, and BP elevation in C.M. classifies his presentation as a hypertensive emergency that warrants a prompt reduction in BP. Sublingual and topical nitroglycerin may help in acutely and temporarily lowering his BP and relieve his chest pain while waiting for more definitive treatment to be implemented.

IV labetalol has been used successfully in hypertensive emergencies.[96–102] Labetalol blocks both β- and α-adrenergic receptors and also may exert a direct vasodilator effect. The β-blockade is nonselective with β-to-α potency of 3:1 for oral and 7:1 for IV. Labetalol is advantageous in C.M. because the immediate onset of action will reduce peripheral vascular resistance without causing reflex tachycardia. Myocardial oxygen demand will be reduced and coronary hemodynamics will be improved, making this agent an excellent choice for patients such as C.M., with anginal symptoms or MI. In addition, IV labetalol does not significantly reduce cerebral blood flow; therefore, it may be useful in patients with cerebrovascular disease.[1,25]

Fenoldopam or nitroprusside could also be used to treat C.M. Fenoldopam could be considered, but C.M.'s history of glaucoma would preclude its use. Additionally, fenoldopam would not be preferred because of its potential for reflex tachycardia and the risk

of worsening ischemia. Treatment with nitroprusside would expose C.M. to the potential risk of cyanide and thiocyanate toxicity with his new-onset acute kidney injury. In contrast, labetalol has been used successfully in patients with renal disease without deleterious side effects.[105,106] Labetalol is eliminated by glucuronidation in the liver, with <5% of the dose being excreted unchanged in the urine.

Contraindications and precautions

Case 16-3, Question 2: What cautions should be exercised when using labetalol in C.M.?

Labetalol's disadvantages are primarily related to its β-blocking effects. Therefore, it should not be used in patients with asthma or obstructive airway disease, heart block greater than first degree, or sinus bradycardia, and it should be used with caution in patients with decompensated HF[97,101,107,108] (see Case 16-2, Question 10). Nonselective β-blockers, such as labetalol, have been associated with an increased risk of moderate or severe asthma exacerbations, as compared with cardioselective β-blockers.[109] None of these are present in C.M. Labetalol has been effective in the treatment of hypertension associated with pheochromocytoma and excess catecholamine states as well as those with rebound hypertension from β-blocker withdrawal.[110] However, because labetalol is primarily a β-blocker, paradoxical hypertension may occur in patients with pheochromocytoma. These individuals have adrenal tumors that excrete high amounts of norepinephrine, which results in relatively unopposed α-1-receptor stimulation.[110] More clinical experience is required before labetalol can be recommended in patients with pheochromocytoma.[6,96]

Case 16-3, Question 3: How should parenteral labetalol be given to C.M.?

IV labetalol can be given by bolus administration or continuous infusion.[96–101] Bolus injections are administered, beginning with 10 to

20 mg given at a rate of 10 mg/min, followed by 20 to 80 mg every 10 minutes until the desired response is achieved or a cumulative dose of 300 mg is reached. The desired response is usually achieved with a mean dose of 200 mg in 90% of patients.[97] The maximal effect occurs within 5 to 15 minutes,[99] and the antihypertensive response may persist for more than 6 hours.[111] Because the rate of BP reduction is accelerated with an increase in infusion rate,[99] a controlled continuous infusion may provide a more gradual reduction in arterial pressure with less frequent adverse effects.[101,112] The infusion can be started at a rate of 0.5 to 2 mg/min and titrated at a rate of 0.5 mg/min every 15 minutes until a satisfactory response is achieved or until a cumulative dose of 300 mg is reached. However, it is important to note that labetalol has a long half-life, and prolonged infusions can lead to accumulation and have been associated with dangerous, potentially fatal cases of delayed hemodynamic compromise.[113] Once the cumulative dose is achieved, therapy should be transitioned to oral dosing as soon as possible.

Parenteral to oral conversion

Case 16-3, Question 4: C.M. was treated with a labetalol infusion and required a cumulative dose of 180 mg to achieve a DBP of 100 mm Hg. His anginal symptoms resolved almost immediately, but 3 hours after the infusion, C.M. became faint and dizzy while ambulating. Should oral labetalol be withheld in C.M.?

Postural hypotension and dizziness are dose related and more commonly associated with the IV route of administration.[103,107] C.M. should remain in a supine position after the IV administration of labetalol, and his ability to tolerate an upright position should be established before permitting ambulation. Oral labetalol can be given to C.M. when his symptoms resolve. There is no correlation between the oral maintenance dose and the total initial IV dose. C.M. should be started on an empiric dose of 200 mg of oral labetalol two to three times per day, and this can be titrated as necessary at ≥1-day

intervals to a range of 400 mg/day to 2.4 g/day in two to three divided doses.

Case 16-3, Question 5: What other side effects can occur with labetalol therapy?

Other side effects commonly associated with labetalol include nausea, vomiting, abdominal pain, and diarrhea in up to 15% of the patients.[107] Scalp tingling is an unusual side effect that has been reported in a few patients after IV administration; it tends to disappear with continued treatment. Other side effects include tiredness, weakness, muscle cramps, headache, and skin rashes.

NITROGLYCERIN

Case 16-3, Question 6: Would parenteral nitroglycerin be an acceptable alternative to labetalol for C.M.?

Hypertensive emergencies in the setting of unstable angina or MI requires an immediate reduction in BP. Nitroprusside has been used successfully, but IV nitroglycerin can have more favorable effects on collateral coronary flow in patients with ischemic heart disease.[114] By diminishing preload, nitroglycerin decreases left ventricular diastolic volume, diastolic pressure, and myocardial wall tension, thus reducing myocardial oxygen consumption.[115] These changes favor redistribution of coronary blood flow to the subendocardium, which is more vulnerable to ischemia. At high dosages, nitroglycerin dilates arteriolar smooth muscles, and this reduction in afterload also decreases myocardial wall tension and oxygen consumption.[116]

IV nitroglycerin has a rapid onset of action and a short duration and is easily titratable. It is generally appropriate to begin IV nitroglycerin in the dose range of 5 to 10 µg/min, increased by 5 µg/min every 3 to 5 minutes up to 20 µg/min. If no response occurs at 20 µg/min, the dose can be titrated by 10 to 20 µg/min every 3 to 5 minutes as needed to control pressure and symptoms. The usual

dose ranges from 40 to 100 µg/min. The major limiting side effects are headache and tachyphylaxis. In general, IV nitroglycerin is well suited for use in patients such as C.M. who have angina or in patients who have hypertensive emergency associated with MI or coronary artery bypass surgery.

HYDRALAZINE

CASE 16-4

QUESTION 1: T.M., a 30-year-old male with a history of chronic glomerulonephritis and poorly controlled hypertension, came to the ED for evaluation of early morning occipital headaches during the past week. He has no other symptoms. He has not taken any BP medication in a month. Physical examination revealed an afebrile male in no acute distress with a BP of 160/128 mm Hg without orthostasis and a regular pulse of 90 beats/min. Funduscopic examination revealed bilateral exudates without hemorrhages or papilledema. The lungs were clear. Cardiac examination was pertinent for cardiomegaly and an S_4 gallop. The remainder of the physical workup was normal.

Laboratory results include the following values:

Hematocrit, 32%
Blood urea nitrogen, 40 mg/dL
Serum creatinine, 2.5 mg/dL (baseline serum creatinine 1.9 mg/dL)
Bicarbonate, 18 mEq/L

Urinalysis reveals 2+ protein, 2+ hemoglobin with 4 to 10 red blood cells per high-power field. The electrocardiogram demonstrates normal sinus rhythm with left ventricular hypertrophy. The chest radiograph is unremarkable.

T.M.'s presentation meets the criteria for a hypertensive emergency (ie, DBP >120 mm Hg and presence of worsening renal function). IV antihypertensive therapy is required for T.M., and he was given 20 mg of hydralazine IV. A repeat BP after 1 hour was 150/100 mm Hg.

What are the advantages and disadvantages of parenteral hydralazine, and when should it be used to acutely lower BP?

Hydralazine is a direct vasodilator that reduces systemic resistance through relaxation of the arterial smooth muscle, with little effect on veins. It is rarely used to treat hypertensive emergencies because its antihypertensive response is less predictable than that of other parenteral agents. Additionally, hydralazine has a prolonged

half-life, which can be problematic if too fast correction or hypotension occurs.[24] It is not consistently effective in controlling crises associated with essential hypertension.

Contraindications

Hydralazine should not be used in patients with coronary heart disease because the reflex tachycardia causes an increase in myocardial oxygen demand, which may result in the development or worsening of ischemic symptoms. In addition, hydralazine should be avoided in patients with aortic dissection because of its reflex cardiostimulating effect. In contrast, hydralazine can be useful in patients such as T.M., who have a chronic renal failure because the reflex increase in cardiac output is accompanied by an increase in organ perfusion.[23]

Dosing and administration

Parenteral hydralazine should be considered an intermediate treatment between oral agents and more aggressive therapy with agents such as clevidipine, nicardipine, fenoldopam, or nitroprusside. It can be given IV or intramuscularly. The onset of action develops slowly over 10 to 80 minutes. The prolonged duration of effect up to as long as 12 hours makes additional dosing requirements unpredictable. Parenteral doses are considerably lower than oral doses because of extensive first-pass metabolism.

OTHER PARENTERAL DRUGS

Case 16-4, Question 2: What are the alternatives to hydralazine for parenteral treatment of hypertensive crisis?

Intravenous enalaprilat

Enalaprilat, the active metabolite of the oral prodrug enalapril, is approved by the U.S. Food and Drug Administration for the treatment of hypertension and has been used to treat severe

hypertension.[117–122] The initial dose is 0.625 to 1.25 mg IV given over 5 minutes and can be repeated every 6 hours, if necessary. To minimize the risk of hypotension, the initial doses should not exceed 0.625 mg in patients receiving diuretics or in patients with clinical evidence of hypovolemia or with a history of HF or hyponatremia. The onset of action is within 15 minutes, but the maximal effect may take 1 to 4 hours. Because only 60% of patients respond to BP reduction within 30 minutes, it cannot be reliably used to acutely lower BP in hypertensive emergencies.[120] Although higher initial doses have been successfully used to achieve BP control,[121] some evidence indicates that initial doses >0.625 mg do not significantly alter the magnitude of enalaprilat's antihypertensive effect.[119] Enalaprilat is also beneficial in patients with HF. Precautions for the use of enalaprilat are similar to those of captopril (see Case 16-1, Question 5). Because of the prolonged time required to achieve an adequate response, limited clinical experience, and variable response rates (especially in Black patients), enalaprilat cannot be recommended for the routine treatment of patients with hypertensive emergencies.[120,122]

Intravenous calcium channel blockers

CASE 16-5

QUESTION 1: H.C. is a 71-year-old male undergoing urgent coronary artery bypass graft surgery after an MI. H.C. has a history of cerebrovascular accident and chronic kidney disease (serum creatinine is stable at 1.6 mg/dL). Two hours after surgery, H.C.'s BP increased from 142/90 to 170/132 mm Hg. H.C. was administered IV nicardipine postoperatively for BP control.

Is nicardipine an appropriate choice for H.C.?

Nicardipine

Postoperative hypertension is typically short-lived and is most commonly seen after neurosurgical, head and neck, vascular, and cardiothoracic procedures (as is the case with H.C.). Treatment is typically only required for 6 hours postoperatively and up to 24 to 48

hours for some who may have persistent hypertension. Adequate control of BP postoperatively is necessary to minimize the risk of cardiovascular, neurologic, or surgical-site complications such as bleeding.[123] When selecting an agent, one should consider therapies with a quick onset and short duration of action as well as established efficacy and safety in the postoperative setting.

Nicardipine is a potent cerebral and systemic vasodilator and a useful therapeutic option in the management of severe hypertension. Its onset of action is within 1 to 2 minutes, and its elimination half-life is 45 minutes, with a terminal half-life of 14 hours after prolonged infusions.[124] Hemodynamic evaluations demonstrated that IV nicardipine significantly decreased mean arterial pressure and systemic vascular resistance and significantly increased cardiac index with little or no change in heart rate.[125] As a dihydropyridine, nicardipine has less negative inotropic activity compared with nondihydropyridines. Titratable IV nicardipine has been studied extensively for use in controlling postoperative hypertension[125–128] and hypertensive emergencies.[129–132]

In the treatment of postoperative hypertension,[125] IV nicardipine was administered as an infusion titrated in the following manner: 10 mg/hour for 5 minutes, 12.5 mg/hour for 5 minutes, and 15 mg/hour for 15 minutes, followed by a maintenance infusion of 3 mg/hour thereafter. The mean response times and infusion rates were 11.5 minutes and 12.8 mg/hour, respectively. The most commonly reported adverse effects included hypotension, tachycardia, and nausea and vomiting. In hypertensive emergency, the recommended initial dose of nicardipine infusion is 5 mg/hour, titrated by 2.5 to 5 mg/hour every 5 to 15 minutes to achieve goal BP with a maximum dose of 15 mg/hour.

In studies of patients receiving nicardipine versus nitroprusside for postoperative hypertension after cardiac endarterectomy and coronary artery bypass grafting, breakthrough BP was controlled more rapidly with nicardipine and required fewer overall dose titrations. In addition, nicardipine was well tolerated and did not lead to an increased risk of complications.[133,134]

Nicardipine is an appropriate choice of therapy for H.C. in the postoperative setting because this agent has a rapid onset of action and provides sustained BP control during the infusion period. It is easily titratable, with a predictable response, and is relatively free of severe adverse effects. Therapy should be titrated to achieve a BP ~10% higher than the patient's baseline. In addition to nicardipine, clevidipine, nitroprusside, nitroglycerin, and labetalol are commonly used to manage perioperative hypertension.[123,135] Nicardipine may be useful in patients with cerebral insufficiency or peripheral vascular disease. Additionally, among patients undergoing cardiac surgery, nicardipine may exert a beneficial effect on pulmonary wedge pressure and cardiac index, as compared to nitroprusside.[136] Because of the potential for reflex tachycardia, it should be used with caution in patients with ongoing coronary ischemia.

Clevidipine, a third-generation dihydropyridine, has also been shown to be useful in controlling BP in hypertensive emergencies and in the perioperative setting.[135,137,138]

Case 16-5, Question 2: What other IV forms of calcium channel blockers are available? Would any of these agents be an appropriate choice of therapy for H.C.?

Nondihydropyridines

Intravenous verapamil (5–10 mg) produces a significant reduction in BP, which occurs within 3 to 5 minutes and persists for up to 6 hours. As a cardiovascular drug, it is primarily used as a rate-controlling agent in the treatment of supraventricular tachycardias.

IV diltiazem is approved for temporary control of the ventricular rate in atrial fibrillation or atrial flutter and for rapid conversion of paroxysmal supraventricular tachycardia.[139–141] Parenteral diltiazem has also been used to control hypertension that occurs intraoperatively and postoperatively[142,143] and in patients with an acute coronary syndrome.[144,145] However, published experience with the use of IV diltiazem for the treatment of severe hypertension is limited.[146,147]

Atrioventricular nodal conduction abnormalities can occur during the administration of IV verapamil or diltiazem. Patients receiving either of these therapies require continuous monitoring by electrocardiogram and frequent BP checks. Intravenous verapamil and diltiazem should be avoided in patients with sick sinus syndrome or advanced degrees of heart block. Until additional information is available, caution should be exercised in using either agent parenterally to lower BP acutely. In addition, use of nondihydropyridines should be avoided when acutely treating any hypertensive patient with concomitant systolic HF owing to their negative inotropic effects.

CASE 16-5, QUESTION 3: What factors should clinicians consider before recommending the use of clevidipine?

Clevidipine

Clevidipine is another IV dihydropyridine calcium channel blocker with arterial-selective vasodilatory properties.[148] Clevidipine is quickly metabolized in extravascular tissue and blood by esterases, leading to a short initial elimination half-life of 1 minute and a terminal half-life of 15 minutes,[149] with complete resolution of hemodynamic effects within 5 to 15 minutes after the end of a 24-hour continuous infusion.[150] Clevidipine demonstrates a quick onset of action of 2 to 4 minutes.[151] These pharmacokinetic and pharmacodynamic properties make it an attractive agent for managing hypertensive emergencies. Clevidipine demonstrated efficacy in the treatment of hypertension in both preoperative and postoperative cardiac surgery patients.[135,152,153] In this setting, therapy was initiated at a rate of 0.3 to 0.4 μg/kg/min. Target BP was a reduction of at least 15% from baseline. The dose was titrated every 90 seconds by doubling the dose up to an infusion rate of 3.2 μg/kg/min, then increasing the dose by 1.5 μg/kg/min to a maximum rate of 8 μg/kg/min. Clevidipine demonstrated a median time of effectiveness within 6 minutes in >90% of the patients who received the study medication.

A systematic review and meta-analysis compared clevidipine with nitroglycerin, nitroprusside, and nicardipine in the management of perioperative hypertension.[135] Clevidipine was more effective in maintaining BP within the target range with a reduction in rates of treatment failure, without an increase in adverse events or atrial fibrillation. Differences in clinical outcomes have not been identified.

Based on the limited data, nondihydropyridines would not be an appropriate choice of therapy for H.C. Additionally, IV verapamil has a long duration of action, which is not an ideal characteristic in the setting of postoperative hypertension. Clevidipine, however, has a rapid onset of action and short duration of action and is effective in controlling BP in the perioperative setting.

Clevidipine infusions can induce reflexive tachycardia with an increased heart rate by up to ~20 beats/min.[150] Clevidipine is formulated in a 20% lipid emulsion and provides 2 kcal/mL of lipids. Clevidipine infusions are typically initiated at a dose of 1 to 2 mg/hour, with titration occurring by doubling the dose at 90-second intervals. When approaching goal BP, the dose may be increased by less than double every 5 to 10 minutes. In general, each 1 to 2 mg/hour increase in dose may produce an approximate reduction in BP of 2 to 4 mm Hg. The recommended maximum dose is 21 mg/hour, which provides 1000 mL (2000 kcal) in a 24-hour period, although the short-term use of doses up to 32 mg/hour has been reported. It should be avoided in patients with serum triglycerides >500 mg/dL, and any remaining drug and associated tubing should be discarded after 12 hours of use. Clevidipine is contraindicated in patients with allergies to soybeans, soy products, eggs, or egg products. This agent is also contraindicated in those with defective lipid metabolism or acute pancreatitis (if accompanied by hyperlipidemia) and in patients with severe aortic stenosis.[151]

Aortic Dissection

TREATMENT

CASE 16-6

QUESTION 1: B.S., a 68-year-old male with a long history of hypertension and nonadherence, presents to the local ED after experiencing the sudden onset of severe, sharp, diffuse chest pain that radiates to his back between his shoulder blades. Significant findings on physical examination include a pulse of 100 beats/min, BP of 200/120 mm Hg, clear lungs, and an S_4 without murmurs. The laboratory data are unremarkable. The electrocardiogram results are interpreted as sinus tachycardia with left ventricular hypertrophy, but no acute changes are noted. The chest radiograph is significant for widening of the mediastinum. An emergency chest computed tomography scan reveals a dissection at the arch of the aorta.

What antihypertensive medication(s) would be most appropriate for B.S., and why?

Dissection of the aorta occurs when the innermost layer of the aorta (the intima) is torn such that blood enters and separates its layers. The ultimate treatment for this type of hypertensive emergency depends on its location and severity; however, the first principle of therapy is to control any existing hypertension with agents that do not increase the force of cardiac contraction or heart rate. This lessens the force that the cardiac impulse transmits to the dissecting aneurysm.

The aim of antihypertensive therapy in aortic dissection is to lessen the pulsatile load or aortic stress by lowering the BP. Reducing the force of left ventricular contractions, and consequently the rate of rise of aortic pressure, retards the propagation of the dissection and aortic rupture.[154,155] The treatment of choice for aortic dissection typically consists of vasodilatory agents such as sodium nitroprusside, nicardipine, clevidipine, or fenoldopam in combination with a β-blocker titrated to a heart rate <60 beats/min.[154,156,157] Labetalol monotherapy has been used as an alternative.[158] These drugs decrease BP, venous return, and cardiac contractility, thus decreasing shear stress to the aorta.

One common regimen is a combination of IV sodium nitroprusside (0.5–2 μg/kg/min) plus IV esmolol.[22,155] This combination can be used as initial therapy for B.S. The concurrent administration of a β-

blocking agent with a vasodilator is desirable because the latter may induce reflex tachycardia in response to vasodilation.

Esmolol is a parenteral cardioselective β_1-blocker with a rapid onset and short duration of action. For the management of hypertensive emergencies, esmolol should be given as a loading dose of 500 to 1000 μg/kg over 1 minute, followed by a maintenance infusion of 50 μg/kg/min and titrated in 50 μg/kg/min increments up to a maximum rate of 300 μg/kg/min. Irritation, inflammation, and induration at the infusion site occur in 5% to 10% of patients.

Hypotension is the most commonly reported adverse event and is directly related to the duration of esmolol administration.[159] However, because of the short half-life, resolution of hypotension occurs within 10 to 30 minutes of discontinuing the infusion, although this can be prolonged with extended infusion durations. Direct vasodilators such as hydralazine should be avoided because they increase stroke volume and left ventricular ejection rate. These effects augment the pulsatile flow and accentuate the sharpness of the pulse wave, increasing mechanical stress on the aortic wall, which may further dissection.[22]

Depending on the location of the dissection, surgical intervention may be required.[156,160] However, until a definitive diagnosis is made, the primary goal is to reduce the BP and myocardial contractility to the lowest level compatible with the maintenance of adequate renal, cerebral, and cardiac perfusion.[22] Aggressive BP control is warranted to minimize target-organ damage and to prevent further dissection or hemorrhage.[155] For aortic dissection, it is generally recommended that a target heart rate <60 beats/min be achieved first, followed by a systolic BP goal of 100 to 120 mm Hg.[161–163]

In addition to nitroprusside, nicardipine and clevidipine have been evaluated as antihypertensives in the management of aortic dissection and can be considered as options. Titration recommendations in this setting are consistent with prior recommendations in Case 16-5, Question 1 and Case 16-5, Question 3.

Shock

Jason S. Haney and Carolyn M. Bell

CORE PRINCIPLES		CHAPTER CASES
1	Shock is a syndrome with multiple etiologies characterized by an impairment of tissue perfusion which, regardless of cause, can lead to cellular dysfunction, organ failure, and death.	
2	The diagnosis of shock is made by the findings of impaired tissue perfusion on physical examination and hemodynamic and laboratory changes consistent with impaired perfusion. Hypotension may or may not be present. Hemodynamic monitoring is vital for the determination of the type of shock and assessment of response to interventions.	**Case 17-1 (Questions 1, 3, 6)** **Case 17-2 (Questions 1, 4, 6)** **Case 17-3 (Questions 1, 2, 6, 8)** **Case 17-4 (Questions 1, 4), Tables 17-2, 17-3, 17-6, Figure 17-1**
3	Hypovolemic shock is caused by a reduction in intravascular volume.	**Case 17-1 (Question 1)**

		Case 17-2 (Questions 1, 2, 4), Tables 17-1, 17-3
4	Resuscitation is required to treat hypovolemic shock to maintain adequate tissue perfusion and oxygenation. This can be achieved by administration of intravenous crystalloids, colloids, or blood products.	**Case 17-1 (Questions 2–7)** **Case 17-2 (Questions 3–6), Tables 17-4, 17-5**
5	The physiologic response to fluid loss or gain is described by the Frank–Starling curve.	**Case 17-2 (Questions 3, 4), Figure 17-2**
6	Cardiogenic shock results from a decrease in the heart's ability to maintain cardiac output that is unrelated to hypovolemia.	**Case 17-3 (Questions 1, 2), Tables 17-1, 17-3, 17-6**
7	Treatment of patients in cardiogenic shock involves stabilization of the patient, optimization of preload, increasing contractility, and reducing afterload if the blood pressure permits. In cases of acute myocardial infarction complicated by cardiogenic shock, early revascularization is priority.	**Case 17-3 (Questions 3–8), Table 17-7, Figure 17-3**
8	Septic shock is a type of distributive shock characterized by a profound vasodilatory response and decrease in blood pressure caused by a dysregulated host response to infection.	**Case 17-4 (Question 1), Tables 17-1, 17-3, 17-8, 17-9**
9	Treatment of septic shock involves stabilization with fluids, vasopressors, and inotropic agents and treatment of	**Case 17-4 (Questions 1-6), Table 17-7**

the underlying condition. Other therapies involve modification of the body's response to infection.

INTRODUCTION

Shock is defined in simple terms as a syndrome of impaired tissue perfusion and oxygenation usually, but not always, accompanied by hypotension. This impairment of tissue perfusion eventually leads to cellular dysfunction, followed by organ damage and death if untreated. Shock may result from one or more situations, causing a reduction of intravascular volume (hypovolemic shock), myocardial pump failure (cardiogenic shock), severe peripheral vasodilation (distributive shock), or obstruction of blood flow in the systemic or pulmonary circulation (obstructive shock). The type of treatment required depends on the etiology.

In recent years, medical support of patients with shock has improved because of better technologies for hemodynamic monitoring, recognition of the value of volume replacement, appropriate use of inotropic and vasoconstrictive agents, and the development of better ways to treat the underlying cause of the shock syndrome. Understanding the principles of shock should further enhance the prompt recognition of patients at risk, rapid initiation of corrective measures, and development of innovative treatment regimens.

CAUSES

Shock is common among patients in the intensive care unit (ICU) and is present in up to one-third of ICU admissions.[1] **Table 17-1** outlines the classification of shock and precipitating events.[2] Recognition of the etiology and underlying pathology of the various

forms of shock is essential for managing this condition. The distinctions among subtypes of shock only apply, however, in the relatively early stages. As the syndrome evolves and compensatory mechanisms are overwhelmed, it becomes increasingly difficult to determine the subtypes because the clinical and pathophysiologic features of advanced shock are the same for all. Also, different types of shock can occur at the same time (eg, a patient with septic shock who is also hypovolemic). The mortality rate for shock remains quite high—as high as 60% to 80% in severe cases—despite recent improvements in its early recognition and management.[1]

Table 17-1
Classification of Shock and Precipitating Events

Hypovolemic Shock
Hemorrhagic
Gastrointestinal bleeding: varices, peptic ulcer
Trauma
Internal bleeding: ruptured aortic aneurysm, iatrogenic, retroperitoneal bleeding, postoperative bleeding, hemorrhagic pancreatitis, postpartum hemorrhage, tumor or abscess erosion into major vessels
Nonhemorrhagic
Gastrointestinal losses: vomiting, diarrhea, external drainage
Renal losses: diabetes mellitus, diabetes insipidus, overuse of diuretics, salt-wasting nephropathies, hypoaldosteronism
Sequestration: ascites, third-space accumulation
Cutaneous: burns, nonreplaced perspiration, and insensible water losses
Cardiogenic Shock
Cardiomyopathic causes
Acute myocardial infarction: left or right ventricular infarction
Myocardial stunning: low cardiac output syndrome, postcardiac arrest
Myocarditis
End-stage cardiomyopathy or severe acute exacerbation of heart failure
Drug-induced: β-blockers

Arrhythmogenic causes
Tachyarrhythmia: atrial fibrillation/flutter, reentrant tachycardia, ventricular tachycardia/fibrillation
Bradyarrhythmia: Mobitz type II second-degree heart block, complete heart block
Mechanical causes
Rupture of ventricular septum or free wall
Papillary muscle or chordae tendineae rupture or dysfunction
Native valvular insufficiency, stenosis, or obstruction
Prosthetic valvular obstruction, mechanical/leaflet failure, or dehiscence
Distributive Shock
Septic: bacterial, fungal, viral, parasitic, mycobacterial
Nonseptic
Anaphylactic: IgE-mediated, nonimmunologic
Neurogenic: spinal cord injury, traumatic brain injury, cerebral damage, severe dysautonomia
Inflammatory: burns, trauma, pancreatitis, air/fat embolism, postcardiopulmonary bypass, postmyocardial infarction, postcardiac arrest
Drug- or toxin-induced: anesthesia, ganglionic and adrenergic blockers, overdoses of barbiturates and narcotics, carbon monoxide, heavy metal, cyanide
Endocrine: adrenal crisis, myxedema coma
Obstructive Shock
Pulmonary vascular: pulmonary embolism, pulmonary hypertension, severe or acute obstruction of pulmonic or tricuspid valve, venous air embolus
Mechanical
Tension pneumothorax or hemothorax
Pericardial tamponade
Constrictive pericarditis
Restrictive cardiomyopathy
Ventricular outflow tract obstruction
Abdominal compartment syndrome

IgE, immunoglobulin E.

PATHOPHYSIOLOGY

Tissue perfusion is a complex process of oxygen and nutrient delivery as well as waste removal. When perfusion is impaired, it sets up a cascade of events that can eventually end in death. Although the etiology of shock is varied, the eventual progression (if untreated) to cell death and subsequent organ dysfunction results from a common pathway of ischemia, endogenous inflammatory cytokine release, and the generation of oxygen radicals. When cells are subjected to a prolonged period of ischemia, anaerobic metabolism begins. This inefficient process results in a decrease in adenosine triphosphate stores and causes the buildup of lactic acid and other toxic substances that can alter mitochondrial function and eventually result in cell death. In the advanced stages of shock, irreversible cellular damage leads to multiple organ system failure, also known as *multiple organ dysfunction syndrome*.

The body produces inflammatory cytokines in response to ischemia, injury, or infection. The phrase *systemic inflammatory response syndrome* (SIRS) is the recommended umbrella term to describe any acute, overwhelming inflammatory response, independent of the cause.[3] This syndrome has best been described in the sepsis literature; however, it can occur after a wide variety of insults, including hemorrhagic shock, infection (septic shock), pancreatitis, ischemia, multitrauma and tissue injury, and immune-mediated organ injury. SIRS is usually a late manifestation of hypovolemic forms of shock. It is uncommon in cardiogenic shock, but is the hallmark of septic shock. SIRS is clinically characterized by profound vasodilation, which impairs perfusion, increases capillary permeability, and can reduce intravascular volume.

CLINICAL PRESENTATION AND DIAGNOSIS

Independent of the pathophysiologic cause, the clinical syndrome of shock progresses through several stages. During each step, the body uses and exhausts various compensatory mechanisms to balance oxygen delivery ($\dot{D}o_2$) and oxygen consumption ($\dot{V}o_2$) in an effort to maintain perfusion of vital organs. Oxygen delivery is determined by the arterial concentration of oxygen multiplied by the blood flow (cardiac output [CO]) (**Fig. 17-1** and **Table 17-2**). Normally, consumption is independent of supply, except at low rates of $\dot{D}o_2$. In some critically ill patients, perfusion is inadequate to meet metabolic demands, and $\dot{V}o_2$ becomes dependent on the supply despite "normal" $\dot{D}o_2$ ranges.

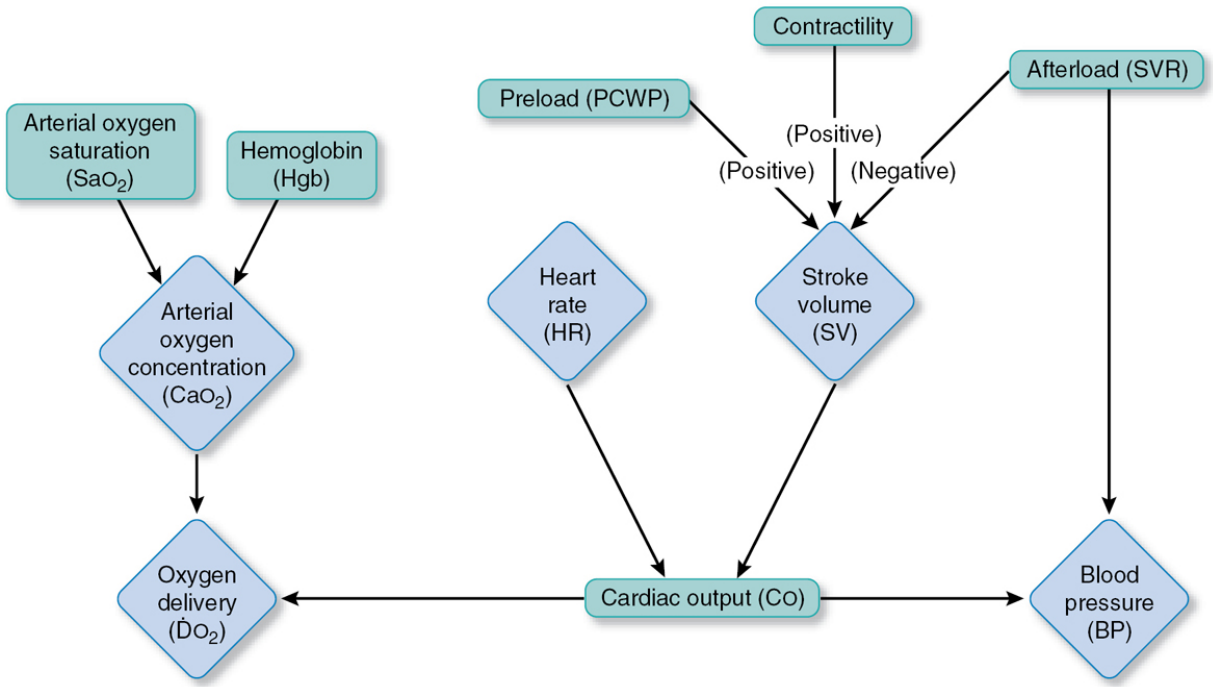

Figure 17-1 Determinants of blood pressure, cardiac output, and oxygen delivery. PCWP, pulmonary capillary wedge pressure. SVR, systemic vascular resistance.

Table 17-2
Normal Hemodynamic Values and Derived Indices

	Definition/Equation	Normal Value	Units
Directly Measured			
Blood pressure (BP) (systolic blood pressure [SBP]/diastolic blood pressure [DBP])	Pressure in the central arterial bed, determined by cardiac output and systemic vascular resistance	90–140/ 60–90	mm Hg
Cardiac output (CO)	Amount of blood ejected from the left ventricle per minute; determined by stroke volume and heart rate CO = SV × HR	4–7	L/minute
Central venous pressure (CVP)[a]	Measures mean pressure in right atrium and reflects right ventricular filling pressure and volume status. Primarily determined by venous return to the heart. The goal in most critically ill patients is 8–12 mm Hg.	2–6	mm Hg[b]
Heart rate (HR) (pulse)	Number of myocardial contractions per minute	60–100	beats/minute
Pulmonary artery pressure (PAP)	*Systolic* (PASP): measures PAP during systole; reflects pressure generated by the contraction of the right ventricle *Diastolic* (PADP): Measures PAP during diastole; reflects diastolic filling pressure in the left ventricle. May approximate PCWP; normal gradient <5 mm Hg between PADP and PCWP	20–30/8–12	mm Hg
Pulmonary capillary wedge pressure (PCWP)	Measures pressure distal to the pulmonary artery; reflects left ventricular filling pressures (*preload*). Usually lower than or within 5 mm Hg of PADP	5–12[c]	mm Hg
Central venous oxygen saturation ($Scvo_2$)	The oxygen saturation of blood returning to the heart; a reflection of oxygen extraction from the upper body	>70	%
Mixed venous oxygen saturation (Svo_2)	The oxygen saturation of blood in the pulmonary artery; a marker of the relationship between CO and total body oxygen consumption	>65	%
Derived Indices			
Cardiac index (CI)	CO per square meter of body surface area (BSA[d]) CI = CO/BSA	2.5–4.2	L/minute/m^2
Left ventricular stroke work index (LVSWI)	Amount of work the left ventricle exerts during systole; adjusted for BSA[d]. A measure of *contractility*, the inotropic state of the myocardium LVSWI = (MAP − PCWP) × SVI × 0.0136	35–85	g/m^2/beat
Mean arterial pressure (MAP)	MAP = [(2 × DBP) + SBP]/3	70–100	mm Hg
Mean pulmonary artery pressure (mPAP)	Average measure of PAP during the entire cardiac cycle; mPAP ≥25 mm Hg at rest is defined as pulmonary hypertension. mPAP = [(2 × PADP) + PASP]/3	12–15	mm Hg
Oxygen delivery ($\dot{D}o_2$)	The amount of oxygen delivered by the body per unit time $\dot{D}o_2 = CO \times Cao_2$, where $Cao_2 = (1.34 \times Hgb \times Sao_2) + (0.0031 \times Pao_2)$	700–1200	mL/minute
Oxygen consumption ($\dot{V}o_2$)	The amount of oxygen consumed by the body per unit time; the product of CO and the difference between the arterial and venous oxygen concentration $\dot{V}o_2 = CO \times (Cao_2 - Cvo_2)$, where $Cvo_2 = (1.34 \times Hgb \times Svo_2) + (0.0031 \times Pvo_2)$	200–400	mL/minute
Coronary artery perfusion pressure (CPP)	The pressure gradient between the coronary arteries and the pressure in either the right atrium or the left ventricle during diastole; a major determinant of coronary blood flow and oxygen supply to the heart CPP = DBP − PCWP	60–80	mm Hg
Pulmonary vascular resistance (PVR)	Primary determinant of right ventricular *afterload* PVR = [(mPAP − PCWP)/CO] × 80 (divide by 80 for Wood units)	20–120 (<2)	dynes·s·cm^{-5} (Wood units)
Stroke volume (SV)	Amount of blood ejected from the ventricle with each systolic contraction SV = CO/HR	60–130	mL/beat
Stroke volume index (SVI)	Stroke volume adjusted for body surface area (BSA[d]) SVI = SV/BSA	30–75	mL/beat/m^2

	Definition/Equation	Normal Value	Units
Derived Indices			
Systemic vascular resistance (SVR)	Measure of impedance applied by systemic vascular system to systolic effort of left ventricle; determined by autonomic nervous system and condition of vessels. Determinant of left ventricular *afterload* SVR = [(MAP − CVP)/CO] × 80	800–1200	dyne·s·cm^{-5}
Systemic vascular resistance index (SVRI)	SVR adjusted for body surface area (BSA[d]) SVRI = SVR × BSA	1680–2580	dyne·s·cm^{-5}·m^2

Ca_{O_2}, arterial oxygen content; Cv_{O_2}, venous oxygen content; Hgb, hemoglobin concentration; PADP, pulmonary artery diastolic pressure; Pa_{O_2}, arterial oxygen tension; PASP, pulmonary artery systolic pressure; Pv_{O_2}, mixed venous oxygen tension; Sa_{O_2}, arterial oxyhemoglobin saturation.

[a]CVP is essentially synonymous with RAP.

[b]2–6 mm Hg = 3–6 cm H_2O (conversion: 1 mm Hg = 1.34 cm H_2O).

[c]May optimally ↑ PCWP to 16–18 mm Hg in critically ill patients.

[d]BSA, body surface area = 1.7 m^2 (average male).

Shock is often first identified by the presence of arterial hypotension and reflexive tachycardia. Although hypotension is often described as the hallmark of shock, it is not necessarily present in all patients.

The diagnosis of shock is based on the findings of impaired tissue perfusion on examination.[1] These findings may include the following:

- Hypotension (systolic blood pressure [SBP] <90 mm Hg, mean arterial pressure [MAP] <65 mm Hg, or at least a 40 mm Hg decrease from baseline)
- Tachycardia (heart rate [HR] >90 beats/min)
- Tachypnea (respiratory rate [RR] >20 breaths/min)
- Cutaneous vasoconstriction: cold, clammy, blue, mottled skin; decreased capillary refill (although not typical of distributive shock)
- Abnormal mental status (agitation, confusion, stupor, or coma)
- Oliguria: urine output <0.5 mL/kg/hour
- Metabolic acidosis (usually because of an elevated blood lactate level)
- Decreased venous oxygen saturation (mixed [Sv_{O_2}], central venous oxygen saturation [Scv_{O_2}]) (reflects a mismatch between oxygen supply [$\dot{D}_{O_2}$] and demand [$\dot{V}_{O_2}$])

Not all these described findings are encountered in every patient with shock, and considerable variability exists in both the rapidity and the sequence of onset. This depends on the severity of the initiating event, the underlying mechanism, and the baseline condition of the

patient, including medications that may alter the clinical presentation. It is important to consider the patient's medical and pharmacologic history, while monitoring for subtle clinical changes that may signal impending deterioration and necessitate immediate intervention.

TREATMENT OVERVIEW

The treatment of patients in shock requires both treatment of the underlying cause of shock, as well as early, aggressive measures to maintain adequate perfusion to vital organs and minimize organ damage. The general measures used are the restoration of volume in patients with hypovolemia, the use of vasopressors or inotropic agents when volume resuscitation is inappropriate or inadequate to maintain perfusion, and careful monitoring of the hemodynamic status of the patient. In sepsis, specific hemodynamic goals have been determined.[4] In other types of shock, specific goals have not been established; however, the principles of ensuring adequate tissue perfusion are the same.

HEMODYNAMIC MONITORING

Hemodynamic monitoring in critically ill patients is mandatory to properly assess and manage various shock states. Noninvasive, minimally invasive, and invasive monitoring techniques can be used to measure or calculate cardiovascular performance and differentiate the causes of various conditions that result in hypoperfusion and organ dysfunction. Less invasive techniques are preferred to minimize risk; however, invasive devices more accurately estimate hemodynamic parameters. The values obtained with hemodynamic monitoring should always be interpreted in the context of other parameters and used in conjunction with a physical examination and clinical judgment.

Noninvasive Monitoring

Noninvasive measures are an important part of hemodynamic monitoring. Clinical examination and vital signs (specifically HR, blood pressure [BP], MAP) provide valuable information as surrogate markers of organ perfusion. An appropriately sized sphygmomanometer can estimate systemic BP, but may be inaccurate in the setting of shock owing to malperfusion of extremities. Cardiac telemetry and/or electrocardiogram (ECG) may help identify a variety of causes for shock (eg, arrhythmia, ischemia, pericarditis). Pulse oximetry is commonly used to measure peripheral arterial oxygen saturation [Sa_{O_2}], which augments respiratory assessment and can be used to determine $\dot{D}_{O_2}$.

ULTRASONOGRAPHY

Transthoracic echocardiography (TTE) can estimate the functional status of the heart and heart valves, visualize the pericardium, and assess response to therapy.[5] Transcutaneous Doppler ultrasound may be used to visualize blood flow through blood vessels or structures and provide estimates of CO, stroke volume (SV), central venous pressure (CVP), and MAP. Ultrasound imaging can also provide dynamic assessment of fluid responsiveness through the evaluation of the collapsibility of the inferior vena cava (IVC) and stroke volume variation (SVV). However, ultrasonography is an intermittent assessment and, therefore, cannot detect acute changes unless the procedure is repeated. In addition, multiple conditions may limit an echocardiogram's ability to produce quality images, such as severe obesity, emphysema, high intrathoracic pressures, and presence of foreign material in the chest cavity.[6]

OTHER NONINVASIVE MONITORING TOOLS

Additional noninvasive methods exist to objectively evaluate certain hemodynamic variables. The Non-invasive Cardiac Output (NICO®, Novametrix Medical Systems, Wallingford, CT, USA) system is able to estimate CO via Fick's principle by measuring partial C_{O_2}

rebreathing through a disposable breathing loop attached to the mechanical ventilator.[7] Bioimpedance and bioreactance technologies can estimate CO, cardiac index (CI), systemic vascular resistance (SVR), and SV by applying electrodes to the thorax and measuring electrical changes during the cardiac cycle.[7] Although each of these methods is intrinsically noninvasive, they all require the patient to be intubated and mechanically ventilated. In addition, none of these methods are currently suitable to replace the more invasive methods of estimating CO because of their inaccuracy in critical illness. Numerous factors can alter the signal quality and accuracy of these methods, including patient movement, electrical interference, arrhythmias, obesity, pleural effusion, pulmonary edema, and aortic valve disease.

Although important, noninvasive measures have limitations, and certain hemodynamic values important for the diagnosis and assessment of illness, as well as the patient's response to therapy, must be measured more invasively at the present time.

Minimally Invasive Monitoring

Indwelling monitoring devices that require insertion into various body parts may be categorized as minimally invasive or invasive. Vascular monitoring devices can be placed within the venous or arterial circulatory system and the location of the terminal end dictates the degree of invasiveness. Minimally invasive devices terminate within the peripheral vasculature, whereas the terminal end of invasive devices dwells inside or near the heart.

ARTERIAL PRESSURE LINE

The arterial line is a common tool in the ICU. It consists of a small catheter placed into an artery (usually the radial or femoral artery) under sterile conditions and attached to a pressure transducer. This allows for continuous measurement of BP and can be more accurate than is a sphygmomanometer in patients with shock, cardiac arrhythmias, calcified arteries, or high SVR. Its accuracy is

dependent on proper calibration of the transducer hub and arterial waveform, patient immobility, and absence of arterial stenosis. The arterial catheter also provides easy access for arterial blood gas (ABG) samples. Arterial lines should never be used for medication administration.

ARTERIAL PULSE WAVEFORM ANALYSIS

Pulse contour analysis devices measure hemodynamic variables such as CO, CI, SV, SVR, SVV, and pulse pressure variation (PPV) using the waveform from a conventional arterial pressure line.[7–9] These devices are increasingly being used in ICUs as an alternative to the pulmonary artery catheter (PAC). Waveform analysis is based on the hypothesis that SV is directly proportional to the area under the systolic portion of the arterial waveform and inversely proportional with impedance.

Several pulse contour methods are available in clinical practice and require various calibration techniques. Uncalibrated methods may be manually calibrated with a measured CO from another source (eg, echocardiogram). LiDCOrapid™ (Medtronic, Minneapolis, MN, USA), Pulsioflex™ (PulsioFlex™ is PULSION Medical Systems, Feldkirchen, Germany), and MostCare™ (Vytech, Padova, Italy) are uncalibrated systems that calculate CO using a detected pulse rate and calculated arterial flow from exclusive algorithms. FloTrac™ is a proprietary transducer that was part of the Vigileo™ monitor (Edwards LifeSciences, Irvine, CA, USA) and one of the earliest adopted uncalibrated methods of hemodynamic monitoring within the ICU. Vigileo™ is no longer commercially available, but FloTrac™ is still available as part of the Edwards EV1000™ clinical platform (Edwards LifeSciences, Irvine, CA, USA).

Calibrated pulse contour systems calculate CO after utilizing either a transpulmonary thermodilution or lithium dilution method for initial calibration. The PiCCO$_2$™ (Pulsion Medical Systems, Munich, Germany) and Edwards EV1000™ are thermodilution-based systems that measure temperature changes within a central artery following the injection of a cold saline bolus through a central venous

catheter. Lithium-based dilution devices, such as the LiDCOplus(™) System (LiDCO Ltd., London, UK), measure diminishing concentrations of lithium following its injection into a central or peripheral vein and a proprietary formula to calculate CO.

Proper calibration and an accurate arterial waveform are vital to the accuracy of pulse contour analysis devices. Arrhythmias, severe aortic regurgitation, cardiac shunts, aortic aneurysms, intra-aortic balloon pumps (IABPs), and extreme hemodynamic instability may limit the accuracy of these devices. Lithium-based devices may be inaccurate in patients with hyponatremia or those receiving neuromuscular blockers and should not be used in patients receiving lithium therapy. Although pulse contour analysis devices compare well with more invasive measurement techniques, an international consensus conference does not currently recommend the newer, less invasive technologies because of lack of validation in patients with shock.[1]

ULTRASONOGRAPHY

Similar to TTE, transesophageal echocardiography (TEE) may provide information to help guide the management of shock states. TEE is more invasive and may provide clearer diagnostic imaging of cardiac structures and function, valvular function, thoracic aorta, and structures surrounding the heart. Because the ultrasound probe is advanced into the esophagus and sedation is generally required for the procedure, a TEE is associated with higher risk. These risks include oversedation, respiratory depression, and physical injury to the oropharynx, esophagus, or lung. Consequently, TEE utilization is generally limited to the perioperative setting with cardiovascular surgery and situations requiring detailed evaluation of valve structure and function, including diagnostic assessments of endocarditis.

Esophageal Doppler ultrasound is an additional minimally invasive technique to monitor CO. The Doppler probe is advanced into the esophagus to continuously measure blood flow in the descending thoracic aorta. CO, CI, SV, SVR, and SVV may be calculated using these measurements. Esophageal Doppler ultrasound has been

shown to have a good correlation with invasive hemodynamic measurements. However, its use is limited by the need for mechanical ventilation, sedation, and proper positioning of the probe within the esophagus when used over extended periods.

OTHER MINIMALLY INVASIVE MONITORING TOOLS

In shock, compromised systemic perfusion and tissue gas exchange result in tissue hypoxia, ischemia, and hypercarbia. Gastric tonometry monitors partial pressure of carbon dioxide (PCO_2) levels within the gut mucosa that are directly influenced by systemic PCO_2 and a surrogate marker of systemic perfusion. Limitations to this process include a lengthy equilibration period (90 minutes) for measurement, increased gastric reflux, and interference from enteral nutrition. Sublingual capnography is a similar, yet simpler, process of tissue PCO_2 monitoring. A PCO_2 gap may be calculated by both methods such as the difference between the arterial partial pressure of carbon dioxide ($PaCO_2$) and measured tissue PCO_2. Excessive PCO_2 gaps (gastric >20 mm Hg and sublingual >25 mm Hg) have been associated with increased mortality.[10,11]

Invasive Monitoring

CENTRAL VENOUS CATHETER

Common in the ICU, the central venous catheter consists of a large-bore catheter usually inserted into a subclavian, jugular, or a femoral vein. It can be used for infusion of fluid and medications or frequent laboratory studies. When attached to a pressure transducer, it can measure the CVP, a static reflection of right ventricular (RV) preload and volume status. A recent shift in clinical practice has occurred as various guidelines call for dynamic rather than static variables (eg, CVP) to guide fluid resuscitation in patients with shock.[1,4] Central venous catheters are preferred to peripheral venous access for administration of large fluid volumes, hypertonic medications, blood products, or vasopressors in patients with shock, but resuscitative

efforts should not be delayed if only peripheral access is available. Central venous catheters that continuously measure the central venous oxygen saturation ($ScvO_2$) have been developed and are becoming more common. These catheters allow for the assessment and monitoring of tissue perfusion and the response to interventions. Low $ScvO_2$ has been associated with worse outcomes.[12–14]

PULMONARY ARTERY CATHETER

The flow-directed, balloon flotation PAC is inserted via a central venous access and positioned into the pulmonary artery (PA).[15] The essential components for hemodynamic monitoring are incorporated in a standard quadruple-lumen catheter. This catheter is composed of multiple lumens, each terminating at different points along the catheter, and enables clinicians to assess intracardiac pressures, determine CO by the thermodilution technique, measure pulmonary arterial pressures, and obtain mixed venous blood samples. These capabilities allow one to evaluate volume status and ventricular performance, derive hemodynamic indices, and determine systemic $\dot{D}o_2$ and $\dot{V}o_2$.

Although the PAC is confined to the right side of the heart and pulmonary vasculature, left ventricular (LV) pressure can be ascertained from the pulmonary capillary wedge pressure (PCWP). A balloon at the tip of the PAC becomes lodged or “wedged” after it is manually inflated. Because forward flow from the right ventricle ceases beyond the wedged PA segment, a static fluid column exists between the LV and the PAC tip during diastole when the mitral valve is open. The PCWP then equilibrates with all distal pressures and thus indirectly reflects left ventricular end-diastolic pressure (LVEDP). Based on the relationship between pressure and volume, the LVEDP is equivalent to the left ventricular end-diastolic volume (LVEDV), and thus PCWP is a surrogate for left-sided *preload.* Significant mitral valve insufficiency or stenosis, LV dysfunction, cardiomyopathy, pulmonary veno-occlusive disease, and positive end-expiratory pressure (PEEP) from respiratory support devices can alter the accuracy of PCWP measurements. Because PCWP

measurements are not always available, the diastolic pulmonary artery pressure (DPAP) may help estimate left-sided preload in the absence of pulmonary hypertension or cardiac tamponade.

The use of PAC has been decreasing in the ICU as newer and less invasive technologies become available. In addition, the PAC is not recommended for routine use in patients with shock because of its lack of a significant effect on mortality, number of days in the ICU or hospital, or cost.[1,3,16,17] In most situations, the PAC is reserved for those patients who specifically require the monitoring of pulmonary artery pressures (PAPs) and oxygenation parameters, such as patients with pulmonary hypertension, refractory shock, RV dysfunction, pericardial illness, cardiac shunts, congenital heart disease, or who are postcardiac surgery.[1,4] More studies are needed to determine the value of PAC data–driven treatment protocols. Complications associated with PAC include atrial or ventricular arrhythmias, thrombotic events, infections, pneumothorax, hemothorax, air embolus, pulmonary infarction, and, very rarely, PA perforation.[16]

INTERPRETATION OF HEMODYNAMIC MONITORING PARAMETERS

Because hypotension alone is not required to define shock, the presence of inadequate tissue perfusion on physical examination is more important than are the numbers obtained by invasive monitoring.[1] The effective interpretation and management of hemodynamic parameters requires a thorough understanding of the physiologic determinants of CO and arterial pressure. Assuming oxygen content of blood is adequate, CO and SVR are the ultimate determinants of Do_2, adequate arterial pressure, and tissue perfusion. As outlined in Figure 17-1, CO may be quantified as the product of SV and HR. SV is determined by preload, afterload, and contractility. Preload is defined as end-diastolic fiber length before contraction and is represented by LVEDV. It is approximated by LVEDP and PCWP. RV preload is reflected by CVP or right atrial pressure (RAP). Afterload is defined as ventricular wall tension developed during

contraction. It is determined by the resistance or impedance the ventricle must overcome to eject end-diastolic volume. LV and RV afterload are determined primarily by SVR and pulmonary vascular resistance (PVR), respectively. Contractility describes the inotropic state of the myocardium and affects the SV and CO independently of preload and afterload. The effects of these factors on hemodynamic parameters are interrelated and complex. Patients often present with features of combined or mixed shock states. Thus, hemodynamic parameters must be assessed carefully when selecting therapeutic interventions that will produce the desired response. A review of the determinants of cardiac performance is found in Chapter 14, Heart Failure. Table 17-2 provides definitions of terms and normal hemodynamic indices.

ETIOLOGIC CLASSIFICATION OF SHOCK AND COMMON MECHANISMS

The most common clinical conditions associated with the major forms of shock are reviewed in the subsequent sections and detailed in Table 17-1. **Table 17-3** describes the common hemodynamic findings for the various forms of shock.

Table 17-3
Hemodynamic Findings in Various Shock States

	Hypovolemic	Cardiogenic	Distributive (Septic)	Obstructive
Heart rate	↑	↑	↑	↑
Blood pressure[a]	↓	↓	↓	↓
Cardiac output	↓	↓	↑/↓[b]	↓
Preload (PCWP)	↓	↑	↔/↓	↑/↓[c]
Afterload (SVR)	↑	↑	↓	↑

PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance.

[a]Patients may be in a state of compensated shock in which blood pressure is normal, but clinical signs of hypoperfusion are evident.

[b]Cardiac output is increased early in sepsis, but can be decreased in late or severe sepsis.

[c]Left ventricular preload is increased in mechanical forms, but decreased in pulmonary vascular forms.

HYPOVOLEMIC SHOCK

Shock secondary to reduced intravascular volume is referred to as *hypovolemic shock*. Whether the primary insult is the external loss of fluid (eg, blood, plasma, or free water) or the internal sequestration of these fluids into body cavities (third spacing), the overall result is reduced venous return or preload (decreased CVP and PCWP) and decreased CO (Table 17-3). The severity of hypovolemic shock depends on the amount and rate of intravascular volume loss and each person's capacity for compensation. Although responses vary, a healthy person may tolerate an acute loss of as much as 30% of his or her intravascular volume.[18] Compensatory mechanisms such as increased HR, myocardial contractility, and SVR are sufficiently

effective for this loss in volume, and measurable falls in SBP are not detected. Losses in excess of 40% generally overwhelm compensatory mechanisms; venous return decreases and the patient's condition can deteriorate to overt shock with hypotension and signs of hypoperfusion. If restorative measures are not taken immediately, irreversible shock and death may result. The most common and dramatic cause of hypovolemic shock is hemorrhagic shock in which intravascular volume depletion occurs as a result of bleeding. Trauma is responsible for most cases of acute hemorrhagic shock; other significant causes are listed in Table 17-1.

Acute Hemorrhagic Shock

CASE 17-1

Question 1: N.G. is a 64-year-old female with a history of peptic ulcer disease, who arrives to the emergency department (ED) with diffuse abdominal pain and bright red blood in her stool over the past 2 days. She is confused and oriented only to person. Her skin is pale and cool, with HR 120 beats/min, SBP 80 mm Hg, and RR 28 breaths/min.

What are the physiologic changes in N.G. in response to her gastrointestinal (GI) bleeding? What are the goals of resuscitation in patients with hemorrhagic shock?

N.G. has lost a significant amount of intravascular fluid directly from her GI tract. She is hypotensive with a compensatory increase in both HR and RR. Her pale, cool skin indicates shunting of blood from the periphery to maintain perfusion of vital organs. Based on her clinical presentation, N.G. is in hypovolemic shock.

The major hemodynamic abnormality in hypovolemic shock is decreased venous return (preload) to the heart, resulting in a decrease in CO. $\dot{D}o_2$ to the tissues is reduced from this and the loss of oxygen-carrying hemoglobin (Hgb). The physiologic response of the body to a sudden decrease in volume (preload) is to activate the sympathetic nervous system to release catecholamines (epinephrine, norepinephrine). The subsequent increase in HR and contractility help maintain CO. The peripheral vasoconstriction caused by the sympathomimetic response helps maintain arterial pressure. In addition, reduction in capillary pressure leads to fluid shifts from the interstitial spaces into the vasculature to increase preload. These responses are effective in maintaining BP in patients with a loss of up to ~30% of the total blood volume. N.G.'s increased HR and signs of peripheral vasoconstriction are consistent with these compensatory changes. Her SBP is still low, however, and she has signs of decreased perfusion to her brain, manifested by confusion and disorientation. Given the severity of her condition, if intravascular losses are not rapidly replaced, myocardial dysfunction may ensue and lead to irreversible shock.

The goals of resuscitation of patients in hypovolemic shock are the correction of inadequate tissue perfusion and oxygenation and limiting secondary insults until steps are taken to control the underlying cause. HR, BP, and urine output have been traditional markers for the adequacy of resuscitation, but reliance on these end points alone is acceptable only in the initial management of hemorrhagic shock. One concern is that patients may persist in a state of compensated shock even after these parameters are normalized.[19] Ongoing deficiencies in $\dot{D}o_2$ to vital organs may progress, and if left untreated, organ dysfunction and death may result. Measurement of base (bicarbonate) deficit and lactate levels can be used to assess the global adequacy of perfusion by tracking trends, ensuring that the levels are decreasing. Metabolic acidosis can signal that resuscitation is incomplete despite normal vital signs.

TREATMENT

Choice of fluid in hypovolemic shock

Case 17-1, Question 2: Is an IV saline solution adequate to compensate for N.G.'s blood loss? What other fluid options are available to resuscitate this patient?

Once an adequate airway is established and initial vital signs are obtained, the most important therapeutic intervention in hypovolemic shock is the infusion of IV fluids. Initially, crystalloids or colloids are used to restore blood volume because blood products are limited, costly, and transfusion of these products carries a risk.[20] Blood products may not be immediately available and are frequently unnecessary to manage mild shock (<20% blood loss). Resuscitative measures should be taken until N.G. can be taken for endoscopic therapy to control bleeding.

Crystalloids versus colloids

Balanced crystalloids (eg, lactated Ringer [LR] solution, Plasma-Lyte® (Baxter Healthcare Corporation, Deerfield, IL, USA)) and isotonic saline (0.9% sodium chloride) are both recommended as resuscitation fluids (**Table 17-4**). Colloidal solutions contain high-molecular-weight molecules that are derived from natural products, such as proteins (albumin), carbohydrates (dextrans, starches), and animal collagen (gelatin), and largely remain in the intravascular space, thereby contributing to colloid oncotic pressure (COP) (**Table 17-5**).

Table 17-4
Composition and Properties of Crystalloids

Solution	Sodium (mEq/L)	Chloride (mEq/L)	Potassium (mEq/L)	Calcium (mEq/L)	Magnesium (mEq/L)	Lactate (mEq/L)	Tonicity Relative to Plasma	Osmolarity (mOsm/L)
5% Dextrose	0	0	0	0	0	0	Hypotonic	253
0.9% Sodium chloride	154	154	0	0	0	0	Isotonic	308
Plasma-Lyte (Baxter)	140	103	10	5	3	8	Isotonic	312
Lactated Ringer's	130	109	4	3	0	28	Isotonic	273
Normosol™ (Hospira)	140	98	5	0	3	0	Isotonic	294
7.5% Sodium chloride	1283	1283	0	0	0	0	Hypertonic	2567

Table 17-5
Composition and Properties of Colloids

Solution	Colloid Type	MWw (kDa)	DS	Sodium (mEq/L)	Chloride (mEq/L)	Potassium (mEq/L)	Calcium (mEq/L)	Glucose (mg/L)	Osmolarity (mOsm/L)
Albumin	Blood derived	67		130–160		≤2			300
Hespan® 6%, B. Braun Medical, Inc Bethlehem, PA	Hetastarch	450	0.7	154	154				309
Hextend® 6%[a], Hospira, Inc Lake Forest, IL	Hetastarch	450	0.7	143	124	3	5	90	307
Voluven®, Fresenius Kabi Norge A.S., Halden Norway	Tetrastarch	130	0.4	154	154				308
Gentran 40, (Baxter Inc; Deerfield, IL)	Dextran 40	40		154	154			50	308
Gentran 70, (Baxter Inc; Deerfield, IL);	Dextran 70	70		154	154			50	308

DS, proportion of substituted to nonsubstituted glucose moieties (higher DS is more resistant to hydrolysis); MWn, arithmetic mean of all particle molecular weight; MWw, weight-averaged molecular weight (number of molecules at each weight multiplied by the particle weight divided by the total weight of all the molecules).

[a]Hextend also contains magnesium 0.9 mEq/L and lactate 28 mEq/L.

The choice of a crystalloid versus a colloid solution to restore blood volume in hemorrhagic shock is controversial. The controversy primarily involves the ultimate distribution of these fluids in the extracellular compartment, which, in turn, depends on their composition. Isotonic solutions (normal saline [NS] or LR) freely distribute within the extracellular fluid compartment, which is divided between the interstitial and intravascular spaces at a ratio of 3:1. This distribution is determined by the net forces of COP and hydrostatic pressure, both inside and outside the capillary vascular space. Consequently, large volumes of crystalloid fluid are required to expand the intravascular space during resuscitation. In contrast, intact capillary membranes are relatively impermeable to colloids, and, therefore, colloids effectively expand the intravascular space with little interstitial loss. Comparatively smaller volumes of colloids than of crystalloids are required for resuscitation, and their duration of action is longer. It is thought that three to four times as much volume of crystalloid compared to colloid is necessary to provide the same degree of volume expansion.

Proponents of crystalloids argue that both intravascular and interstitial fluids are depleted in hypovolemic shock because of the

rapid shifts between the extracellular compartments. Volume replacement of both fluid spaces is best accomplished using crystalloids. In addition, loss of capillary integrity in shock can cause the leak of larger molecules (including colloidal molecules) into the interstitium. This increase in the interstitial oncotic pressure would favor fluid movement out of the vascular space into the tissues, with resultant edema. Crystalloids do not produce allergic or hypersensitivity reactions as many of the colloidal agents do. Colloids can also cause coagulopathies, have been associated with an increased incidence of acute kidney injury, and are much more expensive than are crystalloids.

Proponents of colloids maintain that resuscitation with these solutions more rapidly and effectively restores intravascular volume after acute hemorrhage. For a given infusion volume, colloidal solutions (eg, albumin) will expand the intravascular space two to four times more than crystalloids do, and the intravascular effects persist longer. Traditionally, it has been contended that the larger volumes of crystalloids necessary to restore the vascular space will further dilute the plasma proteins, resulting in a decreased COP and promotion of pulmonary edema. However, clinical studies comparing colloids with crystalloids have failed to show any differences in the development of pulmonary edema. This is likely because of the relatively high alveolar capillary permeability to albumin causing a decreased transcapillary COP gradient. Research suggests that certain subgroups may be at greater risk for the development of pulmonary edema, but considerable variance remains because of differences in physiologic end points, criteria for assessing pulmonary edema, and the extent of shock.

Numerous meta-analyses have compared resuscitation with crystalloids or colloids to find a consensus among divergent clinical trial results. One meta-analysis failed to show a mortality benefit for resuscitation with colloids compared to crystalloids in patients who were critically ill who required fluid replacement as a result of sepsis, trauma, or burns.[21] Mortality outcomes in other meta-analyses reviewing various colloids across different patient groups have been comparable.[22–26] It is important to recognize that study inclusion

criteria (heterogeneity), differences in fluid management, and dosages provide several limitations to these meta-analyses. Fluid resuscitation with starches may be uniquely harmful in patients who are critically ill or undergoing elective surgeries. Multiple analyses have indicated an increase in mortality, need for transfusion of blood products, and need for renal replacement therapy in these patients when starches were used.[21,27,28] Starches should be avoided in these patients until more data are available.

A Cochrane Database meta-analysis found that volume resuscitation with albumin in hypovolemic critically ill patients did not reduce mortality compared to crystalloids and was possibly associated with an increased risk of death in patients with burns or hypoproteinemia.[29] This meta-analysis was heavily influenced by the Saline versus Albumin Fluid Evaluation (SAFE) trial, the largest randomized, prospective trial to evaluate albumin versus NS solution resuscitation in the critically ill.[30] The primary end point of the SAFE trial was 28-day mortality, which showed no difference between albumin and NS solution. No statistical differences were identified in any of the predetermined subgroups (trauma, acute respiratory distress syndrome [ARDS], severe sepsis). A trend toward increased mortality in the trauma patients who received albumin led to a post hoc follow-up study in patients who had traumatic brain injury.[31] A higher mortality rate was seen in patients with severe traumatic brain injury (Glasgow Coma Scale 3–8), who received albumin versus those receiving saline for fluid resuscitation.

More certain differences between colloids and crystalloids are availability and cost. Crystalloid solutions are readily available and remain 20 to 100 times cheaper than are colloidal solutions; therefore, treatment costs can be significantly different and must be considered when choosing between therapies with similar outcomes.[32] Because current evidence does not show mortality benefit with colloids compared to crystalloids and because colloids are more expensive, multiple sets of consensus guidelines do not recommend the routine use of colloids.[33,34] Use of crystalloid solution would be appropriate for N.G. Colloidal products are not needed at this time; instead, they should be reserved for persistent hypotension

despite an appropriate crystalloid challenge.[33] Given the severity of N.G.'s hemorrhagic shock, blood transfusion is indicated and should be transfused as soon as available.[20,35]

Crystalloids

Case 17-1, Question 3: Two large-bore IV catheters are inserted into N.G.'s arms and STAT blood samples are sent for type and cross-match, complete blood count (CBC), prothrombin time (PT), partial thromboplastin time (PTT), and serum chemistry (blood urea nitrogen [BUN], creatinine [SCr], Na, K, Cl, and bicarbonate). Warmed LR solution (1 L) is infused rapidly, and the GI endoscopy suite is notified. N.G.'s SBP has increased to 94 mm Hg, but the bleeding has not stopped. A Foley catheter is inserted to measure urine output. LR is continued, with 500- to 1000-mL boluses ordered to maintain hemodynamic stability while waiting for fully cross-matched blood. Are the doses of LR given to N.G. appropriate? What clinical and objective parameters should be monitored to determine the success of fluid replacement?

Volume Requirements

Isotonic crystalloids equilibrate rapidly between the interstitial and the intravascular spaces at a ratio of 3:1. For every liter of fluid infused, ~750 mL will pass into the interstitium, whereas 250 mL will remain in the plasma. Because determination of blood loss is based solely on clinical assessment and not on quantitative measurements, treatment is best directed by the response to initial therapy rather than to the initial classification. Close observation of hemodynamic status with consideration of the patient's age, particular injury, and prehospital fluid therapy is essential to avoid inadequate or excessive fluid administration.

Crystalloids have been used for decades to manage bleeding. Although crystalloids can transiently expand intravascular volume, they do not provide intrinsic benefit. Large volumes of crystalloids can cause complications such as respiratory failure, compartment syndrome, and increased coagulopathy. Because of these complications, a more restrictive crystalloid resuscitation strategy is employed. A Cochrane systematic review including six randomized

trials that examined timing and volume of fluid administration in bleeding patients found no difference in mortality between restrictive fluid resuscitation and more aggressive fluid resuscitation.[36] Crystalloids are now typically limited to 3 L in the first 6 hours of arrival at the hospital in acutely bleeding patients.[37] The fluid boluses given to N.G. are an appropriate initial measure, and then assessment of her perfusion is vital to determine the need for additional boluses.

Normalization of BP, HR, and pulse pressure (difference between SBP and diastolic blood pressure [DBP]) indicates improved circulation. Signs that actual organ perfusion is normalizing and that fluid resuscitation is adequate include improvements in mental status, warmth and color of skin, improved acid–base balance, and increased urinary output. The minimal acceptable urine output is 0.5 mL/kg/hour for an adult, 1 mL/kg/hour for a child, and 2 mL/kg/hour in an infant age younger than 1 year.[18] Persistent metabolic acidosis in normothermic shock usually indicates the need for additional fluid resuscitation; sodium bicarbonate administration has not been shown to improve mortality or organ failure in patients with severe metabolic acidosis (pH < 7.2) but did decrease 28-day mortality and the composite outcome of 28-day mortality or presence of at least one major organ failure in a subgroup of patients with acute kidney injury.[38] The role of sodium bicarbonate is controversial, but is not recommended unless the pH is <7.2.[19] Monitoring serum lactate and base deficit is important to determine adequate resuscitation.[37] As perfusion improves, lactate and base deficit will decrease; thus, the actual values are not as important as the trend. It is important to note that resuscitation is not defined by just one value or number, such as BP, but by the constellation of indicators of overall perfusion.

Balanced crystalloids versus normal saline

Case 17-1, Question 4: Is there an advantage to using a balanced crystalloid solution (ie, LR) versus NS solution for N.G.?

The optimal resuscitative fluid remains controversial. Historically, intravenous (IV) NS has been the most commonly administered fluid. In recent years, there has been much interest in using balanced crystalloids (eg, LR, Plasma-Lyte, Normosol™, ICU Medical, Inc., Lake Forest, IL, USA) for resuscitation in critically ill patients. NS solution has a supraphysiologic sodium and chloride content, whereas the electrolyte content of balanced crystalloids more closely resembles extracellular fluid (Table 17-4). Large volumes of NS can cause hyperchloremic metabolic acidosis, thereby worsening the tissue acidosis from hypovolemic shock. The SALT Balanced Crystalloids versus Saline in the Intensive Care Unit, with 974 critically ill patients, demonstrated that the incidence of death, new renal replacement therapy, and persistent renal dysfunction were all lower with balanced crystalloids compared to that with NS.[39] Similarly, the Isotonic Solutions and Major Adverse Renal Events Trial (SMART) trial showed a reduction in acute kidney injury with balanced crystalloids in 15,802 critically ill patients.[40] A meta-analysis of 13 trials demonstrated a lower hospital or 28- or 30-day mortality and less new acute kidney injury in patients given balanced crystalloid.[41]

Balanced crystalloids are buffered with a base (eg, lactate, acetate, gluconate). Sodium lactate in LR can cause a minimal increase or less than expected decrease in serum lactate concentrations following fluid resuscitation, particularly in patients with impaired hepatic function, but it does not cause lactic acidosis.[42–44] The lactate buffer is utilized for energy in ischemic conditions and may decrease cellular death.[44] Lactate and acetate are metabolized to carbon dioxide and water and later to bicarbonate. Metabolism of gluconate is not fully understood, but many studies suggest that gluconate is excreted unchanged in the urine. Adverse effects and outcomes between different balanced crystalloids are still being investigated.[45] Recent randomized controlled trials add to a growing body of evidence suggesting that balanced crystalloids decrease morbidity and mortality in critically ill patients and are preferred over NS. LR is an appropriate option for volume resuscitation in N.G.

Hypertonic Saline

CASE 17-1, QUESTION 5: What is the role of hypertonic saline (HS) solution in the setting of hemorrhagic shock?

The presumed advantage of HS (3%–7.5% NaCl) solution as a resuscitative fluid is the smaller volume of fluid required to expand the intravascular compartment compared with isotonic solutions. With a high concentration of sodium, the HS solution exerts an osmotic effect, translocating fluid from the interstitial and intracellular compartments to the intravascular space. Consequently, plasma volume is rapidly expanded to a greater extent than are similar volumes of crystalloid solutions, and systemic BP, CO, and $\dot{D}o_2$ are readily increased. Intracranial pressure is reduced, but to date HS has not been shown to improve outcomes in trauma patients with concomitant head injury.[46] Other studies have shown that HS may have beneficial effects on circulation, inflammation, and endothelial function.[46,47]

Despite these initial positive findings, hypertonic solutions are not widely used because they have failed to improve clinical outcomes. Much of the data regarding HS as a resuscitative fluid in hypovolemic shock is in trauma patients. The Resuscitation Outcomes Consortium performed a multicenter randomized controlled trial of NS, HS, and HS dextran for prehospital resuscitation in patients with hemorrhagic shock. An interim analysis showed no mortality difference between groups and worse coagulopathy with hypertonic solutions. The trial was stopped early owing to futility.[48] No high-quality trials are available in patients with GI bleeding.

Hypertonic solutions are also high-risk medications. HS is prone to dosing and administration errors, particularly when used by clinicians who are unfamiliar with the product. The osmolarity of HS can range from 1026 to 2567 mOsm/L (3%–7.5% NaCl), so infusion through a central line is preferred to minimize phlebitis. HS may cause hypernatremia and hyperchloremic metabolic acidosis, resulting in

rapid fluid shifts between cellular compartments and potentially devastating effects such as osmotic demyelination syndrome. However, most studies have not reported such events, which may be because of a lack of power or the relatively small volumes of HS used for resuscitation.

Blood replacement

Case 17-1, Question 6: N.G. has received 3 L of LR solution to maintain hemodynamic stability. Her current vital signs are BP 98/54 mm Hg, HR 108 beats/min, and RR 30 breaths/min. She is still confused and is becoming more agitated and combative. Urine output has been only 30 mL in the past 30 minutes. Laboratory results include the following:

Hematocrit (Hct), 21% (down from 26%)
Hemoglobin (Hgb), 7.1 g/dL (down from 8.9 g/dL)
pH, 7.14
P_{CO_2}, 34 mm Hg
P_{O_2}, 106 mm Hg
HCO_3^-, 16 mEq/L

Two units of packed red blood cells (PRBCs) are now available, and N.G. is being prepared for the GI endoscopy suite. What is the current status of N.G.'s resuscitation and the need for blood products?

N.G. is still exhibiting signs of inadequate tissue perfusion. Although her BP has improved and her HR has decreased, her mental status has declined, she is oliguric, and her ABG indicates metabolic acidosis. N.G. has not been adequately resuscitated from her hemorrhage, is still actively bleeding, and should receive available blood at this point.

The prior conventional approach to the transfusion of critically ill patients was to maintain the Hgb >10 g/dL or the Hct >30%. It has been argued that these liberal transfusion goals are justified in acutely ill patients, particularly those with cardiovascular disease, because the compensatory mechanisms to maintain tissue $\dot{D}o_2$ are impaired. However, randomized, controlled trials have shown that a restrictive transfusion strategy (target Hgb 7–8 g/dL or transfused if

symptomatic) is associated with equivalent or better outcomes in hemodynamically stable critical care, surgical, and medical patients.[20,35] In acute upper GI bleeding, a restrictive transfusion threshold (Hgb <7 g/dL) compared with a liberal transfusion threshold (Hgb <9 g/dL) was associated with a higher 6-week survival, lower rates of further bleeding, and less adverse effects.[49] Consensus guidelines recommend a transfusion target of 8 g/dL for nonvariceal upper GI bleeds.[34]

In acute hemorrhage, the actual degree of blood loss is not accurately reflected by the Hgb and Hct values, and it also does not take into account the body's ability to compensate for the loss of oxygen-carrying capacity. Because it takes at least 24 hours for all fluid compartments to reach equilibrium, a normal Hct (or Hgb concentration) in the setting of hemorrhagic shock does not rule out significant blood loss or indicate adequacy of transfusion. Only when equilibrium has been reached can these measures be used reliably to gauge blood loss. On the other hand, if cardiopulmonary function is normal and volume status is maintained, an increase in CO can compensate for a reduction in Hgb (O_2 content) to a certain degree (Fig. 17-1).

Because inadequacy of tissue perfusion, and hence $\dot{D}o_2$, is the primary abnormality in shock, the need for transfusion therapy is more accurately determined by the patient's symptoms and oxygen demand, rather than an arbitrary Hct or Hgb value.[20] Calculation of $\dot{D}o_2$ and $\dot{V}o_2$ can be used to determine the adequacy of perfusion. Although these values can be determined using a PAC and arterial and venous blood samples, for practical purposes the patient's response to initial fluid resuscitation and clinical signs of inadequate tissue perfusion are the primary determinants for blood transfusion. Patients who are not acutely bleeding and who do not respond to initial volume resuscitation or who transiently respond but remain tachycardic, tachypneic, and oliguric clearly are underperfused and will likely require blood transfusion. Patients who have acute bleeding or who demonstrate signs of underperfusion should be

considered for transfusion much sooner; thus, N.G. should receive a transfusion.

In acute bleeding, combinations of fresh frozen plasma (FFP), platelets, and PRBCs are needed to treat coagulopathy, but the optimal ratio is unclear. The PROPPR (Pragmatic, Randomized, Optimal Platelet and Plasma Ratios) study compared 1:1:1 versus 1:1:2 (FFP:platelets:PRBC).[50] International guidelines differ in recommendations of FFP:RBC, but agree that platelets should be transfused based on platelet counts.[51–54]

Adverse effects of transfusion

Case 17-1, Question 7: After the transfusion, N.G. has a serum potassium concentration of 4.7 mEq/L compared with 4.2 mEq/L before the transfusion. Could this be a result of the blood product? What other potential acute transfusion-related complications are associated with PRBC administration?

Possible risks of blood transfusions include febrile and allergic reactions, hemolytic reactions, transfusion-associated circulatory overload (TACO), transfusion-related acute lung injury (TRALI), electrolyte abnormalities, infectious disease transmission, coagulopathies, and immunosuppression.[55] Blood products are now safer than before because of improved donor screening, patient identification, hemovigilance, and increased understanding of transfusion-related adverse events. Febrile nonhemolytic, allergic reactions, and delayed serologic transfusion reactions are the most common adverse reactions. Recognition of donor–recipient ABO incompatibility and the signs and symptoms of a transfusion reaction (eg, anxiety, infusion site pain, chills, rigors, fever, hypotension, tachycardia, hemolysis, hemoglobinuria) can prevent unnecessary morbidity and mortality by stopping the infusion and providing supportive therapy.

TRALI and TACO are the most commonly fatal transfusion-related adverse events.[55,56] The pathophysiologic mechanisms of each are complex and incompletely understood. TRALI occurs owing to

activation of recipient neutrophils, which cause capillary endothelial damage and noncardiogenic pulmonary edema. TACO results in pulmonary edema in patients with limited cardiac reserve (eg, the elderly, infant, renal failure, heart failure [HF]), following suboptimal fluid management, or after massive transfusions. Both occur within 6 hours of blood transfusion.[56] No specific treatment is available for either adverse reaction, and management includes supportive care.

Hemolytic transfusion reactions can be classified as immune mediated or nonimmune mediated. Immune-mediated reactions occur when incompatible blood or blood products are transfused, normally owing to mistransfusion events. It is unlikely that N.G. is having a true hemolytic reaction. Banked blood is stored with a citrate anticoagulant additive. With multiple transfusions, the large amount of citrate can cause hypocalcemia and acid–base abnormalities. Hyperkalemia also can occur because transfusion of stored blood causes the release of potassium from hemolyzed (ruptured) red blood cells. The increase in serum potassium observed in N.G. may be from the blood product; however, the average amount of extracellular potassium ranges from <0.5 to 7 mEq/unit of blood, so the transfusion is unlikely the culprit. The increased potassium may simply reflect hemolysis of blood cells in the test tube after the blood draw. In either case, the measured serum concentration of 4.7 mEq/L is not sufficiently high to warrant immediate treatment, but should be monitored.

Blood products and donors are screened for disease; thus, transmission of bacterial or viral illness is rare. It is estimated that the transmission of human immunodeficiency virus or hepatitis C is now <1 in 2 million.[50] Protozoan infection and prion disease are also transmissible through infusion, but are an even lower risk.

Immunosuppression has also been associated with blood transfusions, as evidenced by enhanced graft survival in renal transplant recipients, tumor recurrence in patients with colorectal carcinoma, and postoperative infections. Transfusion-related immunosuppression is multifactorial, but it is most likely caused by the infusion of donor white blood cells (WBCs), which creates a competition between the donor and the recipient leukocytes.

Transfusion-related immunomodulation can be limited by leukoreducing PRBCs before transfusion. The majority of blood in the United States is leukoreduced, but it is not a universal practice primarily because of cost. Patients who are immunosuppressed, undergoing cardiac surgery, or receiving chronic transfusions should receive leukoreduced blood. This mechanism is not, however, the only cause because immunosuppression is associated with autologous blood transfusions as well as the infusion of plasma alone.

Because of the limited supply and potential adverse effects associated with blood, research is ongoing to develop blood substitutes. The ideal agent would have a longer shelf life, a reduced risk of disease transmission, and less risk of transfusion reactions. The agents in various stages of clinical research include the modified hemoglobins and the perfluorocarbons.[57] Problems have occurred with some of the products thus far, such as short half-life, vasoconstriction, GI disturbances, and flulike symptoms. The exact role the blood substitutes would play in transfusions is unclear. No agents are approved, but unlicensed blood substitutes may be available under a U.S. Food and Drug Administration Expanded Access (previously referred to as compassionate use) protocol for patients with life-threatening anemia for whom blood is not an option.

Postoperative Hypovolemia

HYPOVOLEMIA VERSUS PUMP FAILURE

CASE 17-2

Question 1: P.T. is a 58-year-old male who arrives to the ED via ambulance after a motor vehicle accident. He has remained conscious during the event, but his mental status fluctuates between somnolent and agitated with a Glasgow Coma Scale of 10 (moderate injury). Chest computed tomography (CT) reveals a type II proximal descending thoracic aortic injury. P.T. is taken for an emergent surgical repair of his aorta. He has been admitted to the ICU after surgery and is intubated and receiving 60% oxygen. His ABGs are adequate. His initial

postoperative and 2-hour postoperative hemodynamic profiles are as follows (initial parameters in parentheses):

BP (S/D/MAP), 86/44/58 mm Hg (100/52/68 mm Hg)
HR, 96 beats/min (88 beats/min)
CO, 3.2 L/min (4.8 L/min)
CI, 1.9 L/min/m^2 (3.3 L/min/m^2)
CVP, 6 mm Hg (12 mm Hg)
PAP (S/D), 18/8 mm Hg (24/14 mm Hg)
PCWP, 13 mm Hg (18 mm Hg)
SVR, 1080 dyne.sec/cm^5 (1560 dyne.sec/cm^5)
Urine output, 0.4 mL/kg/hour (1.2 mL/kg/hour)
Temperature, 99.32 °F (37.4 °C) to 94.64 °F (34.8 °C)
Hct, 32% (31%)

From the hemodynamic profile, is P.T. hypovolemic or experiencing pump failure after his surgery?

Most of P.T.'s hemodynamic changes are consistent with hypovolemia. These include a drop in BP, CVP, PAP, PCWP, CO, and urine output. The decrease in CVP and PCWP suggests that preload is reduced, resulting in a lower CO. The pulse pressure is narrowed, suggesting that either blood flow or ventricular contractility has decreased. Decreases in pulse pressure correlate with decreases in SV or left ventricular stroke work index [LVSWI]. P.T.'s HR increased slightly, but it is unclear whether he was taking any medications, such as a β-blocker, before his injury. As body temperature rises postoperatively, vasodilation decreases SVR and increases the intravascular space. If intravascular volume is inadequate and increased sympathetic tone cannot generate a sufficient CO, mean BP falls. The decline in urine output reflects a compensatory drop in renal perfusion. The most likely explanation for the hemodynamic change in P.T. is hypovolemia. The PCWP would be higher if P.T. was in cardiogenic shock; however, he also should be evaluated for the occurrence of a perioperative cardiac event (myocardial infarction [MI]). His ABG should be checked to assess oxygen requirements.

CAUSES

CASE 17-2, QUESTION 2: What are the most likely causes of hypovolemia in P.T.?

Common causes of hypovolemia in surgical patients are postoperative bleeding, third spacing, and temperature-related vasodilation. Postoperative bleeding can produce hypovolemia; however, P.T.'s initial and 2-hour postoperative Hct of 31% and 32%, respectively, do not support bleeding as a cause.

After major vascular or bowel surgery and in cases of burns or peritonitis, patients have an internal redistribution of fluids, called *third spacing*, which can result in intravascular volume depletion. It is not unusual for patients to third-space significant amounts of intravascular volume. The interstitial space and bowel walls can sequester large amounts of fluid, and this can produce a state of relative hypovolemia as is occurring with P.T. This is likely in the first 12 to 24 hours after the surgical procedure. P.T. needs a bolus of IV crystalloids for volume repletion. Mild hypothermia is common during operative procedures. Vasodilation occurs as patients warm postoperatively, expanding the intravascular space. If the amounts of IV fluids administered are insufficient to compensate for the increased venous capacitance, BP and CO will decline during the rewarming phase, which can range from 1 to 6 hours. P.T. has rewarmed from 94.64 °F (34.8 °C) to 99.32 °F (37.4 °C) in 2 hours, which is not unusual after a major operative procedure. His temperature could conceivably rise to as high as 100.04 °F (38 °C) to 101.03 °F (38.5 °C) during the first 12 to 24 hours after surgery.

Other considerations include inadequate fluid administration during the operative procedure and the effects of drugs given in the operating room or in the immediate postoperative period (eg, opioids, sedatives, inhaled anesthetics) that cause systemic vasodilation.

VOLUME REPLACEMENT AND VENTRICULAR FUNCTION

Case 17-2, Question 3: How will volume replacement improve P.T.'s CO and perfusion pressure?

The Frank–Starling mechanism indicates that the volume of blood returned to the heart is the main determinant of volume pumped by the heart. Therefore, as venous return is increased, the CO also will increase within physiologic limits until the optimal preload is achieved, at which point further volume has minimal effect on SV (Fig. 17-1). The PCWP, the best indicator of LV preload, and the CVP, a marker of RV preload and overall estimate of volume status, are low because of declining venous return in P.T.

A ventricular function curve can be constructed by plotting a measure of cardiac pumping (CO, SV, or LVSWI) against a measure of preload (**Fig. 17-2**). Two hours after surgery, P.T.'s CVP has fallen from 12 to 6 mm Hg and his CO has fallen from 4.8 to 3.2 L/min. Therefore, additional volume replacement is warranted.

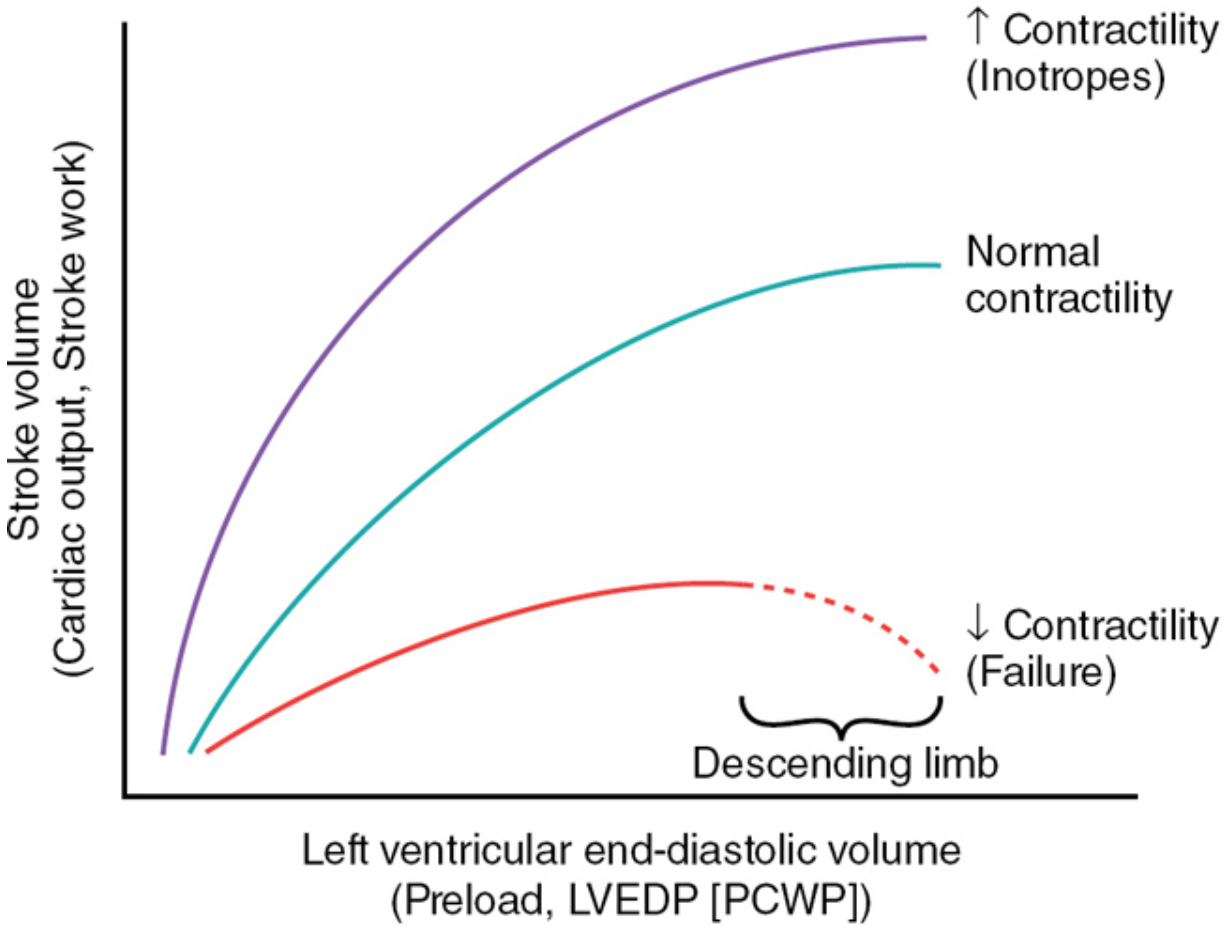

Figure 17-2 Ventricular function (Frank–Starling) curve. In the normal heart, as preload (left ventricular end-diastolic pressure [LVEDP]), measured clinically by pulmonary capillary wedge pressure (PCWP), increases, stroke volume (cardiac output, stroke work) increases until the contractile fibers reach their capacity, at which point the curve flattens. A change in contractility or afterload causes the heart to perform on a different curve. If the contractile fibers exceed their capacity, as with severe heart failure, the heart will operate on the descending limb of the curve.

CASE 17-2, QUESTION 4: P.T. is given a 500-mL bolus of LR solution in 10 minutes, and this results in the following hemodynamic profile (previous values in parentheses):

BP (S/D/M), 96/54/68 mm Hg (86/44/58 mm Hg)
HR, 88 beats/min (96 beats/min)
CO, 3.9 L/min (3.2 L/min)

CI, 2.4 L/min/m^2 (1.9 L/min/m^2)
CVP, 10 mm Hg (6 mm Hg)
PCWP, 15 mm Hg (13 mm Hg)

How can P.T.'s response to the fluid challenge be assessed (see Table 17-2 for normal values)?

According to the Frank–Starling curve, a small change in preload in response to a volume challenge with a minimal change in CO represents a ventricle on the flat portion of the ventricular function curve (Fig. 17-2). Additional fluid therapy given to these patients can increase their risk of pulmonary edema without improving CO. In contrast, a large change in preload in response to a fluid challenge with a significant increase in CO represents a ventricle on the steep portion of the curve. In P.T., the PCWP indicates that he does not have pulmonary edema, and the change in CVP from 6 to 10 mm Hg along with the increase in CO show that he is still responsive to fluid. Thus, it is reasonable to administer more fluid to enhance CO and renal perfusion.

FLUID CHALLENGE

Case 17-2, Question 5: One hour after the 500-mL NS bolus, P.T.'s hemodynamic profile returns to his postoperative state. P.T. is continuing to "third-space" intravascular volume. Based on this information, what strategies can be developed for additional fluid challenges in P.T.?

Acceptable strategies for administering additional fluid challenges to patients with hypovolemia are based on the direction and degree of change in the various hemodynamic parameters in response to a fluid load rather than to their absolute values. CVP has a poor correlation with RV end-diastolic volume because it can be affected by changes in intrathoracic pressure, venous tone, and ventricular compliance (distensibility of the relaxed ventricle or stiffness of the myocardial wall).[58] PCWP and PPV are more predictable markers of fluid status.[1] LV SV (and, thus, pulse pressure) is inversely related to intrathoracic pressures during respiration; SV is maximally affected

at lower filling pressures when the ventricles are operating on the steepest portion of the Frank–Starling curve. An SV that varies at least 12% during a respiratory cycle (between end inspiration and expiration) is highly predictive of a positive response to fluid challenge.[58]

Some practitioners argue that CVP is still an acceptable gauge of fluid responsiveness when used in conjunction with other parameters, including CO, BP, urine output, and tissue perfusion. Using CVP as a guide, an increase in the CVP of 5 mm Hg after a 250- to 500-mL fluid challenge in 10 minutes implies the LV is still functioning on the steep portion of the volume–pressure curve. If the CVP rises abruptly as fluid is given, with a small change in CO, the flat portion of the ventricular function curve has been reached and the IV infusion rate should be slowed. If signs and symptoms of inadequate tissue perfusion worsen or fail to improve and if the CVP remains >10 to 14 mm Hg, fluid challenges should be stopped and inotropic therapy initiated.

Most critically ill patients require a CI >2.5 L/min/m^2 and a PCWP of 12 to 18 mm Hg, or a CVP of 8 to 14 mm Hg to maintain an acceptable MAP of >65 mm Hg. A downward trend in the lactate and base deficit and the change in hemodynamic parameters as well as vital signs and urine output should serve as indicators for whether additional fluid is required.

COLLOIDS

Case 17-2, Question 6: P.T. has received a total of 3.5 L of LR boluses during the past 6 hours and remains hemodynamically unchanged. His urine output has averaged 0.3 mL/kg/hour for the past 4 hours, indicating that volume replacement is inadequate. Given his age and the lack of response to initial crystalloid administration, the decision is made to infuse a colloid solution. How do the colloids compare as a volume expander for P.T., and which agent should be used?

Albumin, the predominant protein in the plasma, accounts for ~80% of the COP, the force that maintains fluid in the intravascular

space.[59] Human serum albumin is the colloidal agent against which all others are compared for volume-expanding properties. It is commercially prepared from pooled donor plasma that is heat treated to eliminate the potential for disease transmission. Albumin 5% solution increases plasma volume by ~80% to 100% of the volume infused, with an initial duration of action of 16 hours.[59] At steady state (3–5 days), ~40% of albumin remains in the intravascular compartment, whereas the rest is in the interstitial compartment. Side effects involve transient clotting abnormalities and anaphylactic reactions (0.5%), both of which are rare.[60] The anaphylactoid reaction is caused by the pasteurization process, causing albumin to polymerize, which produces an antigenic macromolecule. Albumin solutions also contain citrate, which can lower serum calcium concentrations and theoretically lead to decreased LV function. The effects on coagulation and serum calcium are possibly related to the volume of fluid infused rather than to albumin administration.[59] Albumin is available as a 5% solution that is iso-oncotic with the plasma and as a 25% solution that is hyperoncotic. The 5% solution is generally preferred for routine volume expansion, whereas the 25% solution is most useful in correcting hypoproteinemia or intravascular hypovolemia in patients with excess interstitial water. Albumin is subject to availability, as ~1 L of pooled donor plasma is required to produce 20 to 25 g of albumin.

Hydroxyethyl starch (HES) is a synthetic colloid made from amylopectin, which closely resembles human serum albumin but is less expensive. Available as a 6% solution, HES expands the plasma volume by an amount greater than the volume infused because the high oncotic pressure draws water from the interstitial spaces. HES solutions have varying locations and degrees of substitutions on the glucose molecules, which slow enzymatic degradation and confer greater hydrolysis resistance (Table 17-5). HES solutions have complex pharmacokinetics because of their wide range of molecular weights; with an average molecular weight of 69,000 Da and a range of 1000 to 3,000,000 Da. Numerous clinical studies have compared albumin and hetastarch for fluid resuscitation

in patients with and without shock. However, most of these trials were underpowered and there were no significant differences in mortality.[61,62] Although HES has comparable efficacy to albumin, controversy exists regarding the use of HES owing to adverse effects seen with its use. These adverse effects include severe pruritus, coagulopathy, and renal dysfunction and appear to be class-related effects because the newer, lower molecular weight and substitution products are similar.[63–65]

Dose-related reductions in platelet count and transient increases in PT and PTT have been reported with moderate infusions of HES (up to 1500 mL/day), and coagulopathies persist for up to 7 days with larger volumes.[62,64] HES causes factor VIII and von Willebrand factor levels to be lowered beyond that which can be attributed to hemodilution and also increases fibrinolysis.[62] This places patients with von Willebrand disease at greater risk of bleeding. In critically ill patients, particularly those with sepsis, HES is also associated with a dose-related increased risk of acute kidney injury and greater probability of needing renal replacement therapy.[63,64,66–68] HES now includes warnings of excessive bleeding when used in patients undergoing cardiopulmonary bypass as well as a boxed warning that states these products are contraindicated in critically ill patients. Experts argue that HES should not be used because of the potential adverse effects and that other alternatives are available.

Dextrans are colloidal solutions that are synthesized by bacteria from sucrose and are available in 40,000- and 70,000-Da average molecular weight solutions. These products lack adequately powered randomized trials to adequately examine their efficacy or safety.[62] As with HES, dextrans can cause renal dysfunction, bleeding, and anaphylactic reactions. Dextrans can cause acute kidney injury, possibly because of accumulation of dextran molecules within the renal tubules. They increase bleeding by causing dose-related decreased platelet adhesion, increased fibrinolysis, and decreased levels of factor VIII. Dextran solutions are associated with the highest incidence of anaphylactic reactions among all of the colloids.

Because of the lack of superior clinically important outcomes and less favorable safety profiles for HES and dextrans compared to

albumin, it is decided to use albumin for further volume expansion in P.T.

CARDIOGENIC SHOCK

Shock arising primarily from an abnormality in cardiac function constitutes cardiogenic shock. The causes of cardiogenic shock can be separated largely into cardiomyopathic, arrhythmogenic, and mechanical (Table 17-1), although occasionally patients may have a combination of causes. Regardless of the source, the underlying problem in cardiogenic shock is a decrease in CO that is not caused by a reduction in circulating blood volume. This decrease in CO results in the syndrome of shock, organ dysfunction, and death if measures to restore perfusion are not successful.

The most common cause of cardiogenic shock is LV dysfunction and necrosis as a result of acute myocardial infarction (AMI) (see Chapter 13, Acute Coronary Syndrome).[69] Necrosis of the left ventricle can be the result of a single massive MI, numerous smaller events, or severe global cardiac ischemia. Increases in sympathetic tone—seen clinically as increased HR and peripheral vasoconstriction—initially serve to increase CO and maintain arterial pressure. When necrosis exceeds ~40% of the left ventricle, normal compensatory responses can no longer maintain CO, and hypotension and hypoperfusion result. In addition to decreased perfusion to vital tissues and organs, the decrease in CO leads to a reduction in the flow of blood through the coronary arteries, which can lead to infarct extension and a further worsening of cardiac performance.

Recent reports show an increased incidence of cardiogenic shock for unclear reasons, but is likely due in part to improved access to care and diagnosis.[70] Cardiogenic shock occurs in 5% to 12% of AMI cases and is twice as common with ST-elevation MI versus non–ST-segment elevation acute coronary syndrome.[69,71] Higher incidences of cardiogenic shock occur in patients older than 75 years of age,

females, Asian/Pacific Islanders, and those with end-stage renal disease.[72] Cardiogenic shock is the leading cause of death in patients hospitalized with AMI. Early revascularization has improved in-hospital mortality, but the 6- to 12-month mortality rate remains unchanged around 50%.[70,71]

Infarction involving the right ventricle can cause cardiogenic shock, even with normal LV systolic function. In this situation, the volume of blood reaching the left ventricle (preload) is reduced because of the inability of the right ventricle to move blood to the left side of the heart. In most patients with cardiogenic shock and RV infarction, significant LV dysfunction is present as well. Arrhythmias are often associated with worsening perfusion, causing or worsening cardiogenic shock, and poor outcomes.

Patients with chronic HF (see Chapter 14, Heart Failure) usually compensate for their poor cardiac function, but acute exacerbations can cause cardiogenic shock with hypotension, hypoperfusion, and organ dysfunction. Cardiac dysfunction occasionally can be seen with severe sepsis because of increases in the production of inflammatory cytokines that have a depressant effect on the myocardium. However, the cytokine-mediated vasodilation and reduction in afterload usually negates the ability to detect the cardiac dysfunction. A similar picture occurs after cardiopulmonary bypass with heart surgery through activation of the inflammatory cascade.

Mechanical problems are relatively infrequent causes of cardiogenic shock. The systolic function (contractility) of the heart may be normal in this setting, but other defects render the heart unable to eject a normal volume of blood. This limitation of CO may be caused by acute, idiopathic malfunction of cardiac valve(s) or worsening valvular heart disease, infarction (ie, papillary muscle rupture), or infection (ie, endocarditis). Ventricular septal or free wall rupture can also occur, often in the setting of AMI, with the reduction in forward flow related to the inability of the left ventricle to eject a normal volume of blood during systole. Pericardial tamponade (bleeding into the pericardial sac) and tension pneumothorax (air leakage from the lung into the chest) compress the heart, leading to acute diastolic dysfunction. These extracardiac processes are forms

of obstructive shock with physiologic end points that resemble cardiogenic shock.

The symptoms of cardiogenic shock are largely the same as those for other types of shock. Hypotension and signs of inadequate tissue perfusion, such as confusion, oliguria, tachycardia, diminished pulses, cutaneous vasoconstriction, are present in many patients. Differentiating cardiogenic shock from distributive or hypovolemic shock requires further examination. A history of coronary artery disease or symptoms of MI are important findings. Hypovolemia occurs in up to 20% of patients in cardiogenic shock, but patients frequently have signs of volume overload because the heart cannot effectively move blood through the circulation. Peripheral edema and jugular venous distension are seen; lung sounds are diminished; and dyspnea, orthopnea, and/or rales may be present as pulmonary edema develops with LV dysfunction. These findings are particularly evident in patients with severe HF and represent the classic presentation of cardiogenic shock that is termed *cold and wet* owing to the cool extremities and pulmonary congestion. Patients with a previous MI or chronic kidney disease are more likely to present euvolemic or "cold and dry."[71] The least common presentation for cardiogenic shock is "warm and wet," where vasodilation from an SIRS offsets the suppressed CO, allowing for adequate forward flow to perfuse extremities. This subtype is more likely to happen after an MI than in severe HF, but also may reflect a mixed shock state.[69,71]

Because the distinction between cardiogenic and other forms of shock can be difficult to make based on physical examination alone, further testing with invasive hemodynamic monitoring may be required to establish the diagnosis and guide therapy. **Table 17-6** lists the common laboratory, ECG, and chest radiograph findings, and Table 17-3 lists the common hemodynamic findings in cardiogenic shock. CVP may be easily attained, particularly if the patient already has a central line; other hemodynamic findings will require further monitoring tools (eg, PA catheter, echocardiography).

Table 17-6

Typical Findings of Early Cardiogenic Shock

- Arterial blood gas (ABG)
  - Hypoxemia secondary to pulmonary congestion with ventilation–perfusion abnormalities
  - Anion gap metabolic acidosis with a compensatory respiratory alkalosis
- Elevated blood lactate levels (which contribute to the acidosis)
- Complete blood count (CBC)
  - Leukocytosis
  - Thrombocytopenia (if disseminated intravascular coagulation is present)
- Elevated cardiac enzymes if myocardial infarction is present
- Electrocardiogram (ECG)–one or more of the following:
  - T-wave changes indicating infarction
  - Left bundle branch block
  - Sinus tachycardia
  - Arrhythmia
- Chest radiograph
  - Pulmonary edema or evidence of acute respiratory distress syndrome (ARDS)
- Echocardiography
  - Valvular or mechanical problems if present
  - Normal or decreased ejection fraction
- Hemodynamic monitoring—one or more of the following:
  - Reduced cardiac output
  - Arterial hypotension
  - Elevated pulmonary capillary wedge pressure (PCWP) and central venous pressure (CVP)
  - Elevated pulmonary artery pressure (PAP)
  - Elevated systemic vascular resistance (SVR)

Acute Myocardial Infarction

IMMEDIATE GOALS OF THERAPY AND GENERAL CONSIDERATIONS

CASE 17-3

QUESTION 1: J.S. is a 43-year-old male who presents to the ED with chest pain, tingling down his left arm, diaphoresis, nausea, vomiting, and shortness of breath. His pain has been ongoing for 3 hours and is not relieved by rest. He has no known history of cardiac disease and takes no home medications. His BP is 80/40 mm Hg (by cuff) with a weak pulse of 110 beats/min. His RR is 24 breaths/min, and his breathing is shallow. Heart sounds include S_3/S_4 gallops, but no murmurs are heard. The jugular venous pulse is normal.

He has diffuse rales over the lower lung fields with moderate wheezing. J.S. is cold and clammy to touch; however, his temperature is normal. He is restless, anxious, and oriented only to person and place. A 3-mm ST-segment elevation is seen on 12-lead ECG in leads I and aVL. Cardiac biomarkers are pending. ABG measurements, on 4 L/min oxygen via nasal cannula, are the following:

pH, 7.28
$Paco_2$, 32 mm Hg
Pao_2, 94 mm Hg
HCO_3^-, 15 mEq/L
Hct, 31%

What immediate goals of therapy are necessary to stabilize and treat J.S.?

J.S. has signs of "cold and wet" cardiogenic shock with decreased systemic perfusion. His BP is low, HR is elevated, and respiratory status is compromised. J.S. is restless, anxious, and confused, indicating poor cerebral perfusion. His ABG indicates a component of metabolic acidosis secondary to poor systemic perfusion. The ST elevation on the ECG is consistent with an acute anterior MI.

Cardiogenic shock after AMI occurs in only a small percentage of patients, but it carries a high mortality rate. Irreversible organ system dysfunction may rapidly ensue because the compensatory mechanisms fail to maintain tissue perfusion, so its presence can alter the interventional strategy. Treatment of these critically ill patients involves two components: stabilization and definitive treatment. Initial stabilization of the patient must be attained before further evaluation and treatment of the cause of cardiogenic shock can proceed. The goals are to maintain adequate $\dot{D}o_2$ to the tissues and to prevent further hemodynamic compromise. Stabilization includes (a) establishing ventilation and oxygenation (arterial Po_2 should be >70 mm Hg); (b) restoring arterial BP and CO with

vasopressors and inotropic agents, if needed; (c) infusing fluids, if hypovolemic; and (d) treating pain, arrhythmias, and acid–base abnormalities, if present.

While the patient is being stabilized and standard pharmacotherapies are provided as part of early hospital care as discussed in Chapter 13, Acute Coronary Syndrome, reperfusion of the occluded artery is paramount. Coronary occlusion is treated by immediate percutaneous coronary intervention (PCI) if available or, if not, fibrinolytic therapy (unless contraindicated).[69,73]

Early revascularization with PCI or coronary artery bypass grafting (CABG) is preferred in patients with cardiogenic shock complicating AMI, irrespective of time delay.[73] In the SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock) trial, emergency revascularization, compared to immediate medical stabilization (fibrinolysis and IABP), resulted in significantly lower mortality at 1 and 6 years in patients with ST-elevation MI and cardiogenic shock.[74] Long-term mortality was positively correlated with time to revascularization from 0 to 8 hours, confirming that revascularization should be performed as soon as possible. However, a survival benefit for revascularization remains even as long as 54 hours after MI and 18 hours after shock onset.[74] Operator skill is also a consideration, and larger centers with greater experience may have better outcomes than do smaller centers. In settings in which interventional cardiac procedures such as percutaneous transluminal coronary angioplasty or stenting are not readily available, insertion of an IABP and thrombolytic agents should not be delayed, if indicated.

Thrombolytic therapy in AMI may reduce the incidence of subsequent cardiogenic shock, but its value may be limited in patients who have already experienced shock.[74] The effectiveness of thrombolysis is reduced in this setting, possibly because of reduced delivery of the agent to the coronary artery thrombus as a result of hypotension.[75] The use of an IABP to augment coronary artery blood flow may improve the efficacy of thrombolytic agents, but has not been shown to improve mortality.[76,77]

Administration of oxygen is appropriate for patients who have severe dyspnea, hypoxemia (oxygen saturation <90%), or persistent or worsening acidemia (pH <7.3).[71,73] Improving oxygenation may contribute to improved ventricular performance; however, supplemental oxygen could potentially be harmful by causing increased coronary vascular resistance and infarct size, particularly in normoxic patients.[73,78] Invasive mechanical ventilation is indicated when arterial oxygen saturation cannot be maintained above 90% despite 100% oxygen per face mask. Low tidal volume strategies (5–7 mL/kg ideal body weight) are preferred to lower stress and prevent RV failure.[71] Once the patient is intubated, sedation should be provided to alleviate anxiety and discomfort while cautiously monitoring hemodynamic effects.

The arterial pressure must be increased to provide adequate coronary and systemic perfusion to meet oxygen requirements. Some areas of ischemia in the infarct zone may be depressed but viable, provided myocardial oxygen supply exceeds demand. If the myocardial oxygen demands are not met, then myocardial tissue necrosis will expand into the area of ischemia. This results in further hemodynamic impairment and initiates a vicious cycle that can lead to intractable pump failure and irreversible shock. To be effective, treatment of cardiogenic shock should favorably influence the balance between oxygen supply and demand in the ischemic zone. Although correction of volume deficits and early pharmacologic support may prevent the extension of myocardial damage, it must be emphasized that exclusive use of these measures does not improve survival. Therefore, drug therapy must be considered only an interim maneuver to preserve myocardial and systemic integrity while further therapeutic interventions and definitive therapy are being considered.

Optimizing preload to improve CO and systemic perfusion is crucial, especially in patients with RV infarction, but is clinically challenging and can vary over time. In patients with severe LV impairment, increasing intravascular volume can worsen pulmonary congestion. The definitive method of volume assessment is right heart catheterization in conjunction with coronary angiography.[71]

Conservative boluses (250–500 mL) of crystalloid solution are reasonable for patients who are hypovolemic and not exhibiting signs of pulmonary vascular congestion. J.S. currently has signs of pulmonary congestion and RV infarction is not evident; thus, a fluid challenge must be administered cautiously or withheld until hemodynamic monitoring can be established.

Inotropic agents or vasopressors should be used to increase systemic BP and reestablish coronary perfusion in patients with cardiogenic shock and hypotension. However, vasoactive agents have risk because they can increase $\dot{V}o_2$ in ischemic myocardium and potentially extend the area of necrosis in patients with infarct-induced cardiogenic shock. This also exacerbates or increases the risk of ventricular arrhythmias. Therefore, careful selection and titration of agents to the minimal dose that will best preserve myocardium while sustaining systemic arterial pressure and tissue perfusion are essential. Selection of vasoactive medications in cardiogenic shock is generally based on the expected hemodynamic effects and adverse effects of each agent as few clinical outcome data are available to guide decision making. Achieving a MAP >65 mm Hg is the immediate goal of therapy, but it should be adjusted based on adequate perfusion (eg, warm extremities, adequate urine output, improved mental status).[69]

Correction of metabolic acidosis is best accomplished by treating the underlying cause. Improving tissue perfusion by optimizing oxygen content and increasing CO can eventually restore aerobic metabolism and eliminate lactic acid production. The use of sodium bicarbonate to correct lactic acidosis in cardiogenic shock and other critically ill patients is controversial. Sodium bicarbonate can have numerous adverse effects, such as hypernatremia, paradoxic intracellular acidosis, and hypercapnia; conclusive data on its efficacy are lacking. Bicarbonate therapy is recommended only, if at all, when severe acidemia (pH <7.2 or HCO_3^- <10–12 mEq/L) is present.

Postoperative Cardiac Failure

ASSESSMENT BY HEMODYNAMIC PROFILE

CASE 17-3, QUESTION 2: Cardiac catheterization reveals an acute occlusion of the proximal left circumflex artery, but it was not possible to perform a PCI for J.S. He undergoes emergent CABG and arrives in the ICU sedated, intubated, and receiving mechanical ventilation with 50% inspired oxygen. Several hours after admission to the ICU, his BP and urine output have fallen and his skin is mottled and cool. Urine output has fallen from 0.8 to 0.2 mL/kg/hour in the last hour. The chest tube output has been stable at 50 mL/hour. His current hemodynamic profile is as follows:

BP (S/D/M), 86/44/58 mm Hg
HR, 105 beats/min (sinus rhythm)
CO, 3.0 L/min
CI, 1.7 L/min/m^2
Svo_2, 48%
CVP, 14 mm Hg
PAP (S/D), 41/24 mm Hg
PCWP, 24 mm Hg
SVR, 1570 dyne·s·cm^{-5}

What is your assessment of J.S.'s clinical status and hemodynamics?

Clinically, J.S. has signs of hypoperfusion manifested by low urine output; mottled, cool skin; and metabolic acidosis. His decreased Svo_2 shows that he has impaired perfusion owing to his low $\dot{D}o_2$. Evaluation of his hemodynamics will help determine a potential cause for his hypoperfusion and assist with the decision about appropriate therapeutic interventions to prevent his condition from worsening to serious organ dysfunction and death.

Possible causes of shock following cardiac surgery include blood loss, excessive vasodilation from medications or cardiopulmonary bypass–induced inflammation, cardiac ischemia-reperfusion injury, valvular dysfunction, tamponade, HF, or perioperative MI. Another concern is "stunning" of the myocardium caused by surgical trauma, which can take hours to days to resolve.

Hypovolemia should always be evaluated first when assessing hemodynamic profiles. Using vasopressor or inotropic agents in the setting of hypovolemia is rarely effective and could cause further

hypotension or serious adverse effects (eg, cardiac arrhythmias). Also, correction of hypovolemia is relatively straightforward and can be accomplished rapidly. Most patients require no more than 2 to 3 L of crystalloid after cardiac surgery, especially once rewarming is complete. J.S.'s tachycardia, low urine output, low BP, and low CO could indicate volume depletion. However, his Hct is adequate, and he has an elevated CVP, PAP, and PCWP, suggesting that he is not hypovolemic.

Excessive vasodilation is also unlikely in J.S., given that his calculated SVR (afterload) is above normal range. Cardiac tamponade should always be considered after cardiac surgery, and it is usually manifested by very high CVP, PCWP, and PAPs, with significant decreases in CO and BP. Diminished or muffled heart sounds and an inappropriately fluctuating BP with respirations (pulsus paradoxus) will usually accompany an equalization of diastolic pressures during cardiac tamponade. J.S.'s CVP and PCWP are not as high as would be expected in pericardial tamponade, and his chest tube output has remained consistent, suggesting that blood is not accumulating within the mediastinum.

Based on this hemodynamic profile, it appears that J.S. is in shock because of acute HF, most likely from postoperative myocardial dysfunction, although he should also be evaluated for myocardial ischemia or infarction and to rule out early cardiac tamponade. This evaluation should not delay the initiation of therapy.

Patients with cardiogenic shock from an acute event (such as an MI) are usually more critical than are patients who have an acute exacerbation of chronic HF. Patients with HF have compensated over time for the increases in preload and reduced CO, but patients such as J.S. have not had time to develop compensatory mechanisms. His severely depressed CO should be treated immediately to prevent further decompensation.

THERAPEUTIC INTERVENTIONS

Case 17-3, Question 3: The chest radiograph shows moderate pulmonary edema, and rales were heard on auscultation. His ABG measurements on mechanical ventilation with 50% inspired oxygen are pH 7.3, $Paco_2$ 38 mm Hg, Pao_2 90 mm Hg, and HCO_3^- 18 mEq/L. Tamponade is not evident on the radiograph. The ECG shows ST-T-wave changes with some resolution of ST elevation in leads I and aVL, but no indication is seen of a new AMI. Cardiac biomarkers are pending. BP and CO need to be improved to increase perfusion to vital organs. Three therapeutic interventions are available: fluid challenge, vasodilators, and inotropic agents. How would these choices affect J.S.'s ventricular function?

Fluid challenge (increase preload)

Augmentation of preload with a fluid challenge to improve CO is the first option. J.S. has signs of pulmonary edema on chest radiograph, rales on auscultation, and his Pao_2 is 90 mm Hg on 50% inspired oxygen. These clinical signs plus the CVP and PCWP (14 and 24 mm Hg, respectively) indicate volume overload. In addition, increasing the PCWP >18 mm Hg usually does not result in further benefit.[79,80] Giving volume might increase the pulmonary vascular hydrostatic pressure and worsen his pulmonary edema.

Because J.S. is mechanically ventilated, dynamic markers of fluid status may be used to predict fluid responsiveness. Dynamic markers more reliably predict fluid responsiveness than do static variables. Assuming J.S. has an arterial pressure line and is not generating spontaneous breaths, a pulse contour analysis device can be used to determine SVV or PPV. One systematic review indicated that a PPV >12.5% and an SVV >11.6% predicted fluid responsiveness.[81] Ultrasound imaging may provide the degree of IVC collapsibility as an alternative dynamic marker. A >12% change in the IVC diameter predicts responsiveness to fluid administration. A simpler method of dynamic fluid assessment is the passive leg raising (PLR) test in which venous return is increased by shifting blood from the lower extremities toward the heart by lifting the patient's legs passively from the horizontal position to a 45-degree angle. This technique does not require additional equipment and is possible even if J.S. is generating spontaneous breaths. One benefit

of the PLR is predicting fluid responsiveness without giving exogenous fluids. Exogenous fluids are only given if the patient is fluid responsive. J.S. would be considered fluid responsive and a fluid challenge should be given if a 10% to 15% increase in CO is seen after the PLR test.

If a fluid challenge is attempted to enhance preload, 250 to 500 mL of crystalloid solution should be given over 20 to 30 minutes while continuously monitoring the hemodynamic profile and for volume overload. If oxygenation worsens or the PCWP rises without an improvement in CO, fluid challenges should be discontinued. Elevating the preload without appreciably improving CO increases LV wall tension, which is a major determinant of myocardial $\dot{V}o_2$; consequently, myocardial ischemia could develop. Although J.S. has signs of pulmonary edema, diuretics to reduce his volume overload can be detrimental to his CO and BP and should not be used until J.S.'s hemodynamics and signs of hypoperfusion have improved.

Vasodilators (preload and afterload reduction)

A peripheral venodilator will decrease pulmonary venous congestion by reducing preload (CVP and PCWP) and pulmonary vascular hydrostatic pressure. With myocardial ischemia, a reduction in the LV filling pressure may improve subendocardial blood flow, reduce the myocardial wall tension, and shrink the LV radius. The resultant decrease in myocardial $\dot{V}o_2$ will help prevent further depression of cardiac function.

Arterial resistance (afterload) is also elevated in patients with LV failure because of a reflexive increase in sympathetic tone following a drop in systemic arterial pressure. CO is inversely related to resistance to outflow from the left ventricle. Lowering the SVR will decrease resistance to ventricular ejection and shift the ventricular function curve up and to the left, depending on whether an arterial, venous, or mixed vasodilator is used, thereby improving cardiac performance at a lower filling pressure (**Fig. 17-3**).

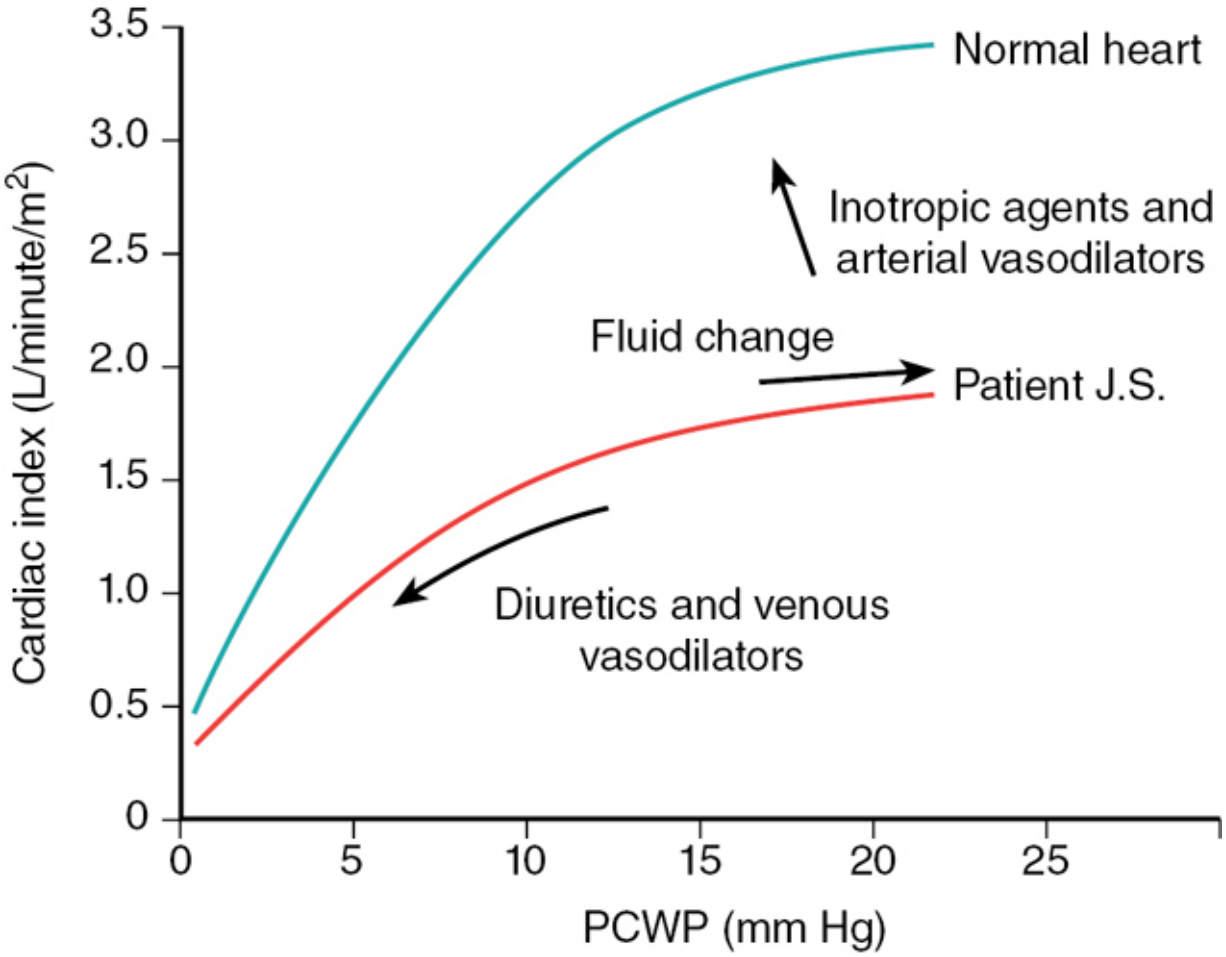

Figure 17-3 Ventricular function curve for J.S. PCWP, pulmonary capillary wedge pressure.

J.S. appears to have LV failure with clinical signs of volume overload and elevations in PCWP and SVR. Vasodilator therapy in this setting will likely improve his CO and, therefore, increase the $\dot{D}o_2$ to the tissues and prevent organ dysfunction. The major risk of vasodilator therapy in J.S., however, is further reduction of an already low MAP. Although the reduction in BP may be offset by an increase in CO, a significant drop in arterial BP could occur, which could decrease perfusion to vital organ systems and exacerbate myocardial ischemia by reducing coronary perfusion pressure. Vasodilator therapy should be reserved for situations of LV failure with elevations in PCWP and SVR and a SBP >90 mm Hg.

Inotropic support

A rapid-acting inotropic agent also can be used to increase myocardial contractility after optimization of the volume status if the CO remains low or inadequate with signs of tissue hypoperfusion.[1] This intervention shifts the ventricular function curve upward and slightly to the left (Fig. 17-3). The disadvantage is that improved CO is accompanied by increased myocardial oxygen demand. Depending on the agent selected, three of the determinants of myocardial $\dot{V}o_2$ could be elevated: HR, contractility, and ventricular wall tension. Therefore, inotropic support is directed at establishing or maintaining a reasonable arterial pressure and ensuring adequate tissue perfusion by improving the CO while minimizing ischemic complications from increased myocardial $\dot{V}o_2$. In the setting of an AMI, inotropic therapy should be considered only after revascularization.

In summary, the most appropriate therapeutic intervention for J.S. at this time would be inotropic support. Dynamic fluid assessment could be considered, but the clinical signs of volume overload and elevated static markers suggest that preload has been maximized; therefore, fluid may worsen J.S.'s pulmonary edema. Although J.S.'s SVR is elevated (1570 dyne·s·cm^{-5}), his BP is low; therefore, initial use of a peripheral vasodilator could jeopardize perfusion. Revascularization via emergent CABG is complete. Thus, inotropic support is an acceptable initial therapeutic intervention to improve CO and tissue perfusion. After a reasonable BP has been established, addition of a peripheral vasodilator could be considered to further enhance CO if needed, and diuretics added to reduce his pulmonary edema.

CASE 17-3, QUESTION 4: Which inotropic agent is the best choice for J.S.?

INOTROPIC AGENTS

Dopamine

Dopamine, a precursor of norepinephrine, has inotropic, chronotropic, and vasoactive properties, all of which are dose

dependent (**Table 17-7**). The distinct ranges noted for dopamine activity are generalizations; responses noted in clinical practice will be patient specific. At <5 μg/kg/min, dopamine stimulates dopaminergic receptors primarily in the splanchnic, renal, and coronary vascular beds. The effect on dopaminergic receptors is not blocked by β-blockers, but is antagonized by dopaminergic-blocking agents such as the butyrophenones and phenothiazines. Depending on the clinical state of the patient, low dosages of dopamine may slightly increase myocardial contractility but usually will not alter HR or SVR significantly.

Table 17-7
Inotropic Agents and Vasopressors

		Receptor Sensitivity			Pharmacologic Effect			
Drug	**Usual Dose**	**α1**	**β1**	**β2**	**VD**	**VC**	**INT**	**CHT**
Dobutamine	2–10 μg/kg/min	+	++++	++	+	+	+++[a]	+
	>10 μg/kg/min	++	++++	+++	++	+	++++[a]	++
Dopamine	<5 μg/kg/min[b]	0	+	0	+	0	++	+
	5–10 μg/kg/min[b]	0/+	++++	++	+	+	+++	++
	10–20 μg/kg/min[b]	+++	++++	+	0	+++	+++	+++
Epinephrine[c]	<0.1 μg/kg/min	+	++++	+++	+	+	++++[a]	++
	0.1–2 μg/kg/min	+++	++++	+++	0	+++	+++[a]	+++
	>2 μg/kg/min	++++	++	+	0	++++	++[a]	+++
Isoproterenol	0.01–0.1 μg/kg/min	0	++++	++++	+++	0	++++	++++
Milrinone	Possible 50 μg/kg bolus, then 0.125–0.75 μg/kg/min	0	0	0	+++[d]	0	+++	0
Norepinephrine[c]	0.02–3 μg/kg/min[f]	++++	+++	+	0	++++	+[e]	++
Phenylephrine	0.5–5 μg/kg/min[f]	++++	0	0	0	++++	0	0
Vasopressin[g]	0.03–0.04 units/min[h]	0	0	0	0	++++	0	0

CHT, chronotropic; INT, inotropic; MAP, mean arterial pressure; VC, peripheral vascular vasoconstriction; VD, peripheral vascular vasodilation.

[a]Dobutamine, milrinone, and epinephrine have more inotropic effect than does dopamine.

[b]Dopamine stimulates dopaminergic receptors at all doses, causing vasodilation in the splanchnic and renal vasculature.

[c]Epinephrine has predominant inotropic effects; norepinephrine has predominant vasoconstrictive effect. Epinephrine may vasodilate at low dosages, and vasoconstrict at high dosages.

[d]Milrinone inhibits phosphodiesterase-3, leading to increased contractility of the myocardium and vasodilation of vascular smooth muscle.

[e]Cardiac output unchanged or may decline because of vagal reflex responses that slow the heart.

[f]Highly variable, titrate to desired MAP.

[g]Vasopressin stimulates V_{1a} receptors to cause vasoconstriction in the periphery.

[h]Dosing for sepsis; in other vasodilatory conditions, it may be titrated from 0.*01* to *0.1* units/min.

At 5- to 10-μg/kg/min, the improved cardiac performance produced by dopamine is through direct stimulation of β_1-adrenergic receptors and indirectly through release of norepinephrine from nerve terminals. Increased β_1-adrenergic receptor stimulation increases SV (inotropic effect), HR (chronotropic effect), and, consequently, CO. These cardiac effects can be blocked by β-blockers. As infusion rates increase >5 μg/kg/min, the α-adrenergic receptors are activated. At this dosage, the vasoactive effects on peripheral blood vessels are unpredictable and depend on the net effect of β_1-adrenergic stimulation, α-adrenergic stimulation, and reflex mechanisms. MAP and PCWP usually will rise. The increased HR, along with the elevated PCWP in J.S., could adversely affect the myocardial oxygen supply to demand ratio. However, it is hoped that the increase in coronary blood flow (caused by the rise in arterial pressure) and the decrease in LV chamber size (associated with the increase in contractility) would tend to offset the increase in myocardial oxygen requirements.

At doses >10 μg/kg/min, dopamine primarily stimulates peripheral α-adrenergic receptors. SVR increases, splanchnic and renal blood flow decreases, and LV filling pressure is raised. Cardiac irritability is a potential complication, and the overall myocardial $\dot{V}o_2$ is increased. The increase in SVR limits CO; thus, infusion rates should be limited to <15 μg/kg/min in patients with cardiac failure.[82]

In a recent trial of 1679 patients with shock, who were randomized to dopamine or norepinephrine for BP support, there was no significant difference in the primary outcome of 28-day mortality.[83] However, patients receiving dopamine had more arrhythmic events and a prespecified subgroup analysis showed an increased mortality

rate in 280 patients with cardiogenic shock. Although these findings may have been because of chance and randomization was not stratified, these findings warrant consideration before selecting dopamine for J.S. and highlight the need for more studies comparing catecholamines in cardiogenic shock.

Dobutamine

Dobutamine, a synthetic catecholamine, is a potent positive inotropic agent with dose dependent but predominant direct β_1-agonist effects and weak β_2- and α_1-adrenergic effects (Table 17-7). With greater β_2-vasodilatory than α_1-vasoconstrictive actions, dobutamine reduces SVR and PVR. The reduction in SVR may be caused by a reflex decrease in vasoconstriction secondary to enhanced CO. Unlike dopamine, dobutamine does not release endogenous norepinephrine or stimulate renal dopaminergic receptors.[84]

Studies assessing dobutamine in cardiac failure demonstrate consistent increases in CO and SV, with reductions in PCWP and SVR. The reduction in filling pressures, as indicated by a lowered PCWP, results in a decrease in LV wall tension and myocardial $\dot{V}o_2$. Consequently, coronary perfusion pressure and myocardial oxygen supply is improved.

Compared with dopamine, dobutamine has equal or greater inotropic action. Dobutamine lowers PCWP and SVR with increasing doses, whereas dopamine may increase PCWP and SVR with increasing doses.[85] The effect on HR is variable; however, evidence suggests that dobutamine is less chronotropic than is dopamine at lower infusion rates. In the clinical setting, dobutamine may be preferred in patients with depressed CO, elevated PCWP, and increased SVR with mild hypotension (SBP >70 mm Hg) and no signs or symptoms of shock. The increase in CO may not be sufficient to raise the BP in a patient who initially is moderately to severely hypotensive (SBP <70 mm Hg) or with signs or symptoms of shock. Dopamine may be recommended in patients with mild hypotension and symptoms of shock, whereas norepinephrine is reserved for patients with an SBP <70 mm Hg.[86,87] Given the

concern of increased mortality with dopamine monotherapy in patients with cardiogenic shock, the combination of dopamine or norepinephrine with dobutamine may be preferred in patients with depressed CO, normal or moderately elevated PCWP, and moderate or severe hypotension.[82,83,87]

Epinephrine

Similar to dopamine and dobutamine, epinephrine has dose-dependent hemodynamic effects (Table 17-7). At lower infusion ranges (<0.1 μg/kg/min) epinephrine stimulates β_1-adrenergic receptors, causing increases in HR and contractility. As the dose increases, more α_1-receptor stimulation occurs, resulting in vasoconstriction and corresponding increases in SVR.

The favorable hemodynamic effects (increased CO and BP) make low-dose epinephrine an attractive option for J.S.; however, epinephrine can induce hyperglycemia through gluconeogenesis and has been shown to increase lactate levels compared with other vasopressors and inotropic agents.[88] J.S. already has signs of acidosis (pH 7.28, HCO_3^- 15 mEq/L), and increased lactic acid production by epinephrine could be detrimental to his organ function. Epinephrine should be reserved for patients with a markedly depressed CO in conjunction with severe hypotension.

In summary, very few comparable studies of inotropic agents in this setting have been conducted; thus, the selection of agent is often based on the expected clinical benefit as well as individual experience with the drugs.[69,89] None of the choices are without risk because they could adversely affect the myocardial oxygen supply to demand ratio and could further extend the area of ischemia or necrosis. J.S. would benefit from an increase in his CO, as well as in his MAP. The team elects to start J.S. on dobutamine and dopamine infusions.

SELECTION AND INITIATION OF THERAPY

Case 17-3, Question 5: At what doses should you initiate a dobutamine and dopamine infusion in J.S.? What therapeutic outcomes are anticipated at these doses and during what time? What adverse effects may be encountered with these infusions?

J.S. has a MAP of 58 mm Hg, CI of 1.7 L/min/m^2, PCWP of 24 mm Hg, and HR of 105 beats/min. Goals of therapy are to increase the CI to ≥2.5 L/min/m^2, maintain a MAP of at least 65 mm Hg (preferably >70 mm Hg, depending on clinical signs of hypoperfusion), reduce the PCWP to 12 to 18 mm Hg, and maintain an HR of <125 beats/min. A urine output of ≥0.5 mL/kg/hour is desirable. Reasonable initial infusion rates would be dopamine 5 μg/kg/min and dobutamine 2 μg/kg/min. These doses should increase cardiac contraction and CO, resulting in an increase in renal blood flow. The onset of effect is rapid and the half-life short (~2 minutes) for both agents, with steady-state conditions generally achieved within 10 minutes of initiation of therapy. This allows dose titration every 10 minutes based on patient tolerance.

Because the onsets of action are within minutes, J.S. can be reevaluated and the infusion rates can be alternately titrated upward by 1 to 2 μg/kg/min every 10 minutes, depending on the hemodynamic data. The response to both agents is highly variable among patients; thus, careful titration using the lowest effective infusion rates is advised.

Adverse effects encountered with both infusions include increased HR, angina, arrhythmias, headache, tremors, nausea, and vomiting. The increases in contractility and HR caused by dobutamine and dopamine pose additive risk of tachyarrhythmias and can increase myocardial $\dot{V}o_2$, leading to ischemia in patients with coronary artery disease.

Dobutamine could lower the MAP, adversely affecting coronary perfusion pressure. Another limiting factor to dobutamine is tolerance to its hemodynamic effects with long-term continuous use. A decline in CO and HR has been seen after prolonged infusion and is most likely caused by downregulation of β_1-receptors. Of concern,

evidence suggests that inotropic agents can be associated with an increased risk of mortality in patients with HF despite the improvement of symptoms and hemodynamic indices.[90]

Dopamine might elevate the PCWP, thereby decreasing coronary perfusion pressure. Extravasation of large amounts of dopamine during infusion can cause ischemic necrosis and sloughing. At higher dosages, α_1-adrenergic effects are more prominent, causing peripheral arterial vasoconstriction and increases in afterload, preload, and myocardial oxygen demand as well as ischemia.

CASE 17-3, QUESTION 6: Dobutamine and dopamine are titrated from 2 to 4 µg/kg/min and 5 to 6 µg/kg/min, respectively, in J.S. during the next 2 hours. A repeat chest radiograph shows slight worsening of pulmonary edema. The following hemodynamic profile is obtained (previous values are in parentheses):

BP (S/D/M), 105/60/75 mm Hg (86/44/58 mm Hg)
HR, 140 beats/min (105 beats/min)
CO, 5.3 L/min (3 L/min)
CI, 3 L/min/m^2 (1.7 L/min/m^2)
CVP, 11 mm Hg (14 mm Hg)
PCWP, 22 mm Hg (24 mm Hg)
SVR, 1493 dyne·s·cm^{-5} (1570 dyne·s·cm^{-5})
Urine output, 0.4 mL/kg/hour (0.2 mL/kg/hour)
Hct, 33% (31%)

Do these data indicate a favorable or an adverse hemodynamic effect from dobutamine and dopamine in J.S.?

Dobutamine at 4 µg/kg/min and dopamine at 6 µg/kg/min have established a trend in the desired direction for CI; however, the HR has increased significantly. The SVR and PCWP have not changed appreciably, and the urine flow has increased. The SV (CO/HR) has only increased from 28 to 38 mL/beat; thus, the increase in CO has resulted from both the chronotropic and the inotropic effects of these agents. As a net response, the dobutamine and dopamine have most likely adversely affected the myocardial oxygen supply to demand ratio; however, this cannot be established definitively. J.S. should be monitored closely for signs of myocardial ischemia.

Milrinone

Case 17-3, Question 7: The clinician decides that an HR of 140 beats/min is unacceptable in J.S., who presented with an AMI. Subsequent attempts to taper the dobutamine to lessen the induced tachycardia without dropping the CI and perfusion pressure are unsuccessful. Milrinone is suggested as an alternative to dobutamine. What hemodynamic changes would you expect with milrinone in J.S.? Does milrinone offer any advantages compared with dobutamine?

Milrinone increases intracellular adenosine monophosphate (AMP) levels by inhibiting phosphodiesterase-3 within the sarcoplasmic reticulum of cardiac myocytes and vascular smooth muscle, leading to increased contractility of the myocardium and vasodilation of vascular smooth muscle (Table 17-7). The increased CO and decreased SVR are accompanied by an increased lusitropic effect. Milrinone produces fewer chronotropic and arrhythmogenic effects than do catecholamines, but, similar to dobutamine, can decrease SVR and cause hypotension. Moreover, milrinone has a longer half-life than does dobutamine, making it difficult to use as monotherapy for cardiogenic shock. The combination of dopamine, norepinephrine, or vasopressin with milrinone would offset some of milrinone's hypotensive effects. Although milrinone has not been shown to improve outcomes in patients who are post-AMI with cardiogenic shock, it could be beneficial in patients with adequate BP, who have downregulated β-receptors (chronic HF or β-agonist use), recently received β-blockade, or with catecholamine dose-limiting arrhythmias.

Dobutamine has equivalent or greater inotropic action than does dopamine, and, as mentioned earlier, dobutamine causes less tachycardia, so it may be better to remove dopamine in this patient. A decrease of 20% of the current dopamine infusion rate (1–2 μg/kg/min) every 10 to 15 minutes is reasonable. Just as with upward titration of therapy, steady state should be achieved within 10 minutes. When tapering vasoactive agents, it is prudent to let the patient stabilize hemodynamically at new infusion rates for a period that exceeds the time to achieve a new steady-state plasma

concentration. After each reduction in the infusion rate, hemodynamic data can be assessed. The major difference between the two agents is the effect of dopamine on α_1-receptors. With dobutamine's greater clinical effect on β_2-receptors compared to α_1-receptors, J.S. may experience a decrease in the SVR. A decreased SVR should allow for an increased CI, but J.S. should be monitored carefully because his MAP is relatively low and any major reduction in SVR could lead to further BP reduction.

CASE 17-3, QUESTION 8: Dopamine is tapered off and dobutamine is increased to 5 µg/kg/min for J.S. His HR decreased to 105 to 110 beats/min within the next hour. Despite these changes and initiation of ventilatory support by tracheal intubation, J.S. continues to show signs of deterioration with progressive obtundation and loss of bowel sounds. His systemic arterial pressure has continued to decline. Preload reduction was attempted previously with nitroglycerin; however, the BP reduction was intolerable. A repeat hemodynamic profile shows the following values (previous values in parentheses):

BP (S/D/M), 86/40/55 mm Hg (105/60/75 mm Hg)
HR, 132 beats/min (105 to 110 beats/min)
CO, 3.2 L/min (5.3 L/min)
CI, 1.8 L/min/m^2 (3 L/min/m^2)
Svo_2, 42% (48%)
CVP, 16 mm Hg (11 mm Hg)
PCWP, 28 mm Hg (22 mm Hg)
SVR, 992 dyne·s·cm^{-5} (1493 dyne·s·cm^{-5})
Urine output, 0.1 mL/kg/hour (0.4 mL/kg/hour)
Pao_2, 75 mm Hg (90 mm Hg)
$Paco_2$, 42 mm Hg (38 mm Hg)
pH, 7.24 (7.3)
HCO_3^-, 17 mEq/L (18 mEq/L)

The ECG shows atrial tachycardia with occasional premature ventricular contractions. What therapeutic alternatives can be considered at this time?

J.S. is still in "cold and wet" cardiogenic shock, and his tissue perfusion continues to deteriorate as evidenced by a further reduction in urine output, a loss of bowel sounds, continuing acidosis, and obtundation. Because his systemic arterial pressure

and tissue perfusion have declined, additional support with a potent vasopressor and the insertion of an IABP or other percutaneous ventricular assist device are indicated. The combination of dopamine and dobutamine previously resulted in intolerable tachycardia, so other therapies should be considered.

Phenylephrine

Phenylephrine is a pure α-adrenergic agonist (Table 17-7) that leads to vasoconstriction and an increased SVR. The lack of β-adrenergic effects can make phenylephrine an ideal vasopressor in patients with other forms of shock who are experiencing atrial or ventricular arrhythmias. However, in cardiogenic shock, phenylephrine will further increase afterload on the weak heart without increasing cardiac contractility. Phenylephrine should only be considered in patients with certain mechanical forms of cardiogenic shock (ie, valvular issues, outflow tract obstruction).[69] Otherwise, phenylephrine should be avoided in patients such as J.S. because it will likely further decrease CO.

Norepinephrine

Norepinephrine is a potent α-adrenergic agonist that vasoconstricts arterioles at all infusion rates, thereby increasing SVR and systemic arterial and coronary perfusion pressures (Table 17-7). Unlike phenylephrine, norepinephrine also stimulates β_1-adrenergic receptors, resulting in increased contractility and SV. However, HR and CO usually remain constant or may decrease secondary to the increased afterload, and baroreceptor-mediated reflex increases in vagal tone. Although coronary perfusion pressure is enhanced as a result of the elevation in diastolic pressure, myocardial $\dot{V}o_2$ also is increased. Consequently, myocardial ischemia and arrhythmias may be exacerbated and LV function further compromised.

Infusions of norepinephrine are begun at 0.01 to 0.05 μg/kg/min and titrated upward to achieve a MAP >65 mm Hg. Adverse effects of norepinephrine are related mostly to excessive vasoconstriction and compromise of organ perfusion. Administration should be

through a central IV line because local subcutaneous necrosis and sloughing can result from peripheral IV extravasation. Prolonged infusion of larger doses will transiently exert a beneficial effect by diverting blood flow from the peripheral and splanchnic vasculature to the heart and brain; however, this ultimately can compromise capillary perfusion to the extent that end-organ failure, particularly renal failure, ensues.

Again, it must be emphasized that pharmacologic support for J.S., particularly the use of norepinephrine, is only an interim maneuver to temporarily maintain hemodynamic function. J.S. should continue to be monitored for signs of myocardial ischemia and the need for further revascularization procedures. Patients who cannot be stabilized with pharmacologic intervention, and in whom systemic or myocardial perfusion is becoming compromised, may require further support through insertion of a mechanical circulatory assist device.

Mechanical circulatory support

When drug therapy is ineffective in stabilizing patients in cardiogenic shock, mechanical intervention should be considered. Mechanical interventions can rapidly stabilize patients with cardiogenic shock, especially those with global myocardial ischemia or infarction complicated by mechanical defects, such as papillary muscle rupture or ventricular septal rupture. In fact, mechanical support has been associated with improved survival rates in patients with AMI complicated by cardiogenic shock when implanted before initiating vasoactive support or PCI.[91] Sometimes, combined inotropic support and intra-aortic balloon counterpulsation are required to maintain an acceptable BP (MAP >65 mm Hg) and CI (>2.2 L/min/m^2).

The IABP is the most commonly used mechanical assist device in cardiogenic shock.[69] It is designed to improve coronary arterial perfusion pressure and reduce afterload, providing short-term reperfusion of the ischemic myocardium.[92] A 20- to 50-mL balloon catheter is inserted into the femoral or axillary artery and advanced to the proximal descending aorta just distal to the left subclavian artery. Balloon inflation and deflation are synchronized with the ECG

to inflate at the onset of diastole and deflate at the onset of systole. The inflated balloon in diastole increases coronary perfusion by elevating the mean aortic pressure. The rapid deflation of the balloon at the onset of systole decreases afterload and modestly improving CO (<1 L/min).[92] The enhanced myocardial perfusion provided by IABP may reduce vasopressor requirements, thereby further decreasing myocardial $\dot{V}o_2$. Occasionally, IABP augmentation is sufficient to allow the institution of vasodilators (eg, nitroprusside) or inodilators (eg, milrinone). IABP support should be discontinued as soon as the patient stabilizes or complications develop. Aortic regurgitation, aortic dissection, and aortic stents are absolute contraindications to IABP use, whereas aortic aneurysm, severe peripheral arterial disease, and major arterial reconstruction surgery are relative contraindications. Complications associated with the IABP increase with longer duration of use and include vascular injury, hematoma, thrombocytopenia from the mechanical destruction of platelets, thromboembolism because of the large, thrombogenic surface area, and limb ischemia because of reduced blood flow in the artery into which the IABP catheter is inserted. A stable cardiac rhythm is necessary for proper function. Heparin anticoagulation is usually given with IABP to reduce the risk of limb ischemia and thromboembolism. Infectious complications are uncommon when the use is limited to <7 days.

The use of IABP support in cardiogenic shock has declined because of the lack of compelling evidence showing benefit.[93] The IABP- SHOCK II study randomly assigned patients with cardiogenic shock following AMI who were expected to undergo early revascularization to receive optimal medical therapy with or without IABP support.[94] The investigators found no mortality benefit at 30 days, 6 months, or 12 months and no differences between groups for all secondary end points.[94,95] Limitations to this study include multiple crossovers to the IABP group that may represent sicker patients, clinician- dependent revascularization strategy (culprit vs multivessel PCI), and the low rate of IABP insertion before PCI. Additional reviews of IABP use in cardiogenic shock have found no differences in 30-day mortality and an increase in the risk of bleeding

complications and stroke.[92,96] Guidelines recommend IABP support as reasonable to consider for patients requiring circulatory support after ST-elevation MI.[73]

Newer percutaneous devices that directly augment CO and decrease the load on the left ventricle have been developed.[92] The percutaneous versions of the Impella® axial flow pumps (Impella 2.5® Abiomed, Inc., Danvers, MA, USA/CP®/RP®) are placed in the cardiac catheterization laboratory, avoiding major cardiac surgery. The left-sided devices (Impella 2.5® Abiomed, Inc., Danvers, MA, USA and CP®) are advanced from the common femoral artery and passed retrograde across the aortic valve into the left ventricle. A CO of 2.5 to 4 L/min can be maintained as blood enters the device from the left ventricle and is ejected into the ascending aorta. In cases of RV failure, the Impella RP® can be inserted similarly to a PAC to pump blood from the IVC to the PA at flows >4 L/min. Systemic anticoagulation is required with these devices. Impella® devices are contraindicated in patients with ventricular thrombi, moderate-to-severe aortic valve disease, mechanical aortic valve, or severe peripheral artery disease. Impella®-related complications include vascular injury, thrombosis, limb ischemia, valve injury, arrhythmias, thrombocytopenia, bleeding, and hemolysis.

Unlike the IABP, the Impella® devices continuously unload the ventricle and support arterial pressure, independent of heart function and rhythm. Despite providing superior hemodynamic support, Impella® devices have not been shown to reduce mortality rates compared with IABP.[69,71] However, early implantation of the Impella® before PCI has been independently associated with improved survival to discharge.[91,97,98] They are best used for early stabilization and temporary circulatory support until revascularization or more definitive therapy is available.

The TandemHeart® (TandemLife, Pittsburgh, PA, USA) is an extracorporeal, centrifugal, continuous-flow mechanical circulatory support device.[69,71] A cannula is advanced from the femoral vein into the left atrium through an atrial septal puncture. Oxygenated blood from the left ventricle is aspirated and pumped into the systemic arterial circulation via the femoral artery. This process unloads the

left ventricle and increases peripheral tissue perfusion. A major limitation to the use of TandemHeart® is the requirement for a skilled physician to implant the device via a transseptal puncture. The TandemHeart® is approved for short-term use in cardiogenic shock because it delivers flow up to 4 L/min and achieves 80% to 90% unloading of the left ventricle. However, it has not been shown to improve mortality in these patients. Systemic anticoagulation is required for this device. Because of the unique cannular approach, the TandemHeart® can be used in patients with aortic valve disease, aortic valve prostheses, or ventricular thrombi when Impella® devices are contraindicated. Contraindications for the TandemHeart® include severe peripheral artery disease, left atrial thrombus, and ventricular septal defect. Complications of the TandemHeart® include bleeding requiring transfusions, disseminated intravascular coagulation, vascular injury, limb ischemia, cardiac tamponade, thromboembolism or air embolism, and hemolysis.

Venoarterial extracorporeal membrane oxygenation (VA-ECMO) is an additional temporary measure of cardiovascular and respiratory support.[69,71] Venous blood is drained, oxygenated, and returned to the systemic circulation using a centrifugal pump. VA-ECMO can support both ventricles with flow rates >4 L/min and may be used in combination with other therapies (ie, IABP, Impella®). Similar to other mechanical support devices, systemic anticoagulation is required for VA-ECMO. Relative contraindications include advanced age (older than 75 years), life expectancy under 1 year, severe peripheral vascular disease, advanced liver disease, and neurologic injury. Potential complications of VA-ECMO include limb ischemia, thromboembolism, stroke, bleeding, hemolysis, infection, and aortic valve insufficiency. Utilization has increased in recent years, but there are no randomized trials investigating its efficacy.[69] VA-ECMO is the device of choice for patients with cardiac arrest, refractory shock with hypoxemia, or biventricular HF. The need for experienced physicians will undoubtedly limit the use of VA-ECMO to experienced medical centers.

In summary, J.S.’s condition has continued to deteriorate since his admission to the ICU. Attempts at stabilizing his hemodynamic

parameters with dopamine and dobutamine have failed. This is evidenced by inadequate tissue perfusion, which is reflected clinically by his continued lactic acidosis, decreased urine output, reduced bowel sounds, and central nervous system obtundation. Norepinephrine and epinephrine should be considered at this point to restore intra-arterial pressure and tissue perfusion. Although early mechanical circulatory support was likely part of the optimal treatment course, synergistic support with intra-aortic counterpulsation or an Impella® device should be considered for J.S.

DISTRIBUTIVE SHOCK

Distributive shock is characterized by an overt loss of vascular tone, causing acute tissue hypoperfusion. Although numerous events such as anaphylaxis, vasoplegia, or neurogenic causes can initiate distributive shock, most cases are readily reversed by supportive measures and treatment or elimination of the underlying cause.

SEPTIC SHOCK

Distributive shock secondary to sepsis, or septic shock, is associated with a high mortality rate, reflecting the limited therapeutic options available at this time. Over 1,500,000 cases of sepsis syndrome are seen annually in the United States. Mortality rates are as high as 50%.[99] The combination of degree of organ dysfunction and number of failing organs is the strongest predictor of death. Epidemiologic studies show that ~25% of cases of sepsis syndrome eventually result in septic shock. It has been projected that the incidence of sepsis will increase 1.5% per year mainly because of the disproportionate growth of the elderly in the U.S. population, increasing burden of chronic health conditions, rising numbers of patients who are immunocompromised, and multidrug-resistant infections.[4,99–102]

The Guidelines Committee of the Surviving Sepsis Campaign—an international consortium of professional societies involved in critical

care, infectious diseases, and emergency medicine—defines *sepsis* syndrome as life-threatening organ dysfunction caused by a dysregulated host response to infection (see **Table 17-8** for definitions).[4] Organ dysfunction is identified as an acute change in total Sequential Organ Failure Assessment (SOFA) score by at least 2 points consequent to the infection (see **Table 17-9** for SOFA calculation). In patients without preexisting organ dysfunction, the baseline SOFA score is assumed to be zero. Persons with an overall SOFA score of ≥2 may have a 25 times higher risk of mortality compared to those with a score <2. Other screening tools include systemic inflammatory response syndrome (SIRS) criteria, National Early warning Score (NEWS), or Modified early warning Score (MEWS). When hypotension persists despite adequate fluid resuscitation and requires vasopressor support to maintain a MAP of ≥65 mm Hg while also having a serum lactate level <2 mmol/L, it is termed *septic shock*. Septic shock is associated with a higher risk of mortality. Persons most at risk for septic shock are those who are immunocompromised or have underlying conditions that render them susceptible to bloodstream invasion. Groups at risk include neonates, the elderly, patients with acquired immune deficiency syndrome, alcoholics, childbearing females, and those undergoing surgery or who have experienced trauma. Other predisposing factors include coexisting diseases such as diabetes mellitus, malignancies, chronic hepatic or renal failure, and hyposplenism; exposure to immunosuppressant drugs and cancer chemotherapy; and procedures such as insertion of urinary catheters, endotracheal tubes, and IV lines.

Table 17-8

Third International Consensus Definitions for Sepsis and Septic Shock

Infection	Pathologic process caused by the invasion of normally sterile tissue or fluid or body cavity by pathogenic or potentially pathogenic microorganisms. (Noted exception: *Clostridium difficile* colitis does not occur in a sterile colon.)
Bacteremia	The presence of viable bacteria in the blood.

Sepsis	Life-threatening organ dysfunction caused by a dysregulated host response to infection.
Organ dysfunction	Identified as an acute change in total SOFA score ≥2 points consequent to the infection.
Septic shock	A subset of sepsis in which underlying circulatory and cellular/metabolic abnormalities are profound enough to substantially increase mortality. Persistent sepsis-induced hypotension requiring vasopressors to maintain MAP ≥ 65 mm Hg and having a serum lactate level >2 mmol/L despite adequate fluid resuscitation. Patients who are on inotropic or vasopressor agents may not be hypotensive at the time that perfusion abnormalities are measured.
Multiple organ dysfunction syndrome	Presence of progressive organ dysfunction in an acutely ill patient, such that homeostasis cannot be maintained without intervention.

MAP, mean arterial pressure; SOFA, sequential organ failure assessment.

Septic shock is characterized initially by a normal or high CO and a low SVR (Table 17-3). Hypotension is caused by the low SVR and alterations in macrovascular and microvascular tone, which result in maldistribution of blood flow and volume. Changes in the microvasculature can lead to loss of normal microvascular autoregulatory mechanisms, resulting in constriction of capillaries, changes in cellular rheology, fibrin deposition, and neutrophil adherence. This causes vascular “sludging” and, in some cases, arteriovenous shunts that bypass capillary beds. Loss of intravascular fluid caused by increased vascular permeability and third spacing of fluid further adds to hypovolemia.[103] In an effort to compensate for the changes in volume and SVR, the body goes into a hyperdynamic state and increases CO. Most patients exhibit myocardial dysfunction as manifested by decreased myocardial compliance, reduced contractility, and ventricular dilation, but they maintain a normal CO, because of tachycardia and cardiac dilatation, which increases or maintains preload.[104] Although the cause of, and mechanism for, this abnormality is not fully understood, it is not believed to be attributable to myocardial ischemia. Rather, it is thought to be caused by one or more circulating inflammatory mediators, such as cytokines (eg, interleukin [IL]-1), tumor necrosis factor-α (TNF-α), platelet-activating factor, arachidonic acid, nitric oxide (NO), and reactive oxygen species. In late septic shock, the body is no longer able to compensate because of the cardiac effects of the inflammatory mediators and resultant myocardial edema, thus resulting in a decreased CO. The end product of this complicated pathway is cellular ischemia, dysfunction, and, eventually, cellular death unless the chain of events is interrupted.

The complex pathogenesis of sepsis is more fully understood now, but some of the exact mechanisms are still not completely clear. The

changes that take place during sepsis are caused by the immunologic host response to infection, which involves inflammatory (SIRS) and immunodepressive (compensatory anti-inflammatory response) mediators that are present from the onset of the immune response.[105]

The inflammatory stage of sepsis is initiated by an infection with a microorganism, most commonly bacterial. Organisms can either enter the bloodstream directly (producing positive blood cultures) or may indirectly elicit a systemic inflammatory response by locally releasing their toxins or structural components at the site of infection. The binding of these toxins to cell receptors promotes proinflammatory cytokine production, primarily TNF-α and IL-1. These toxins stimulate the production and release of numerous endogenous mediators that are responsible for the inflammatory consequences of sepsis. The cytokines act synergistically to directly affect organ function and stimulate the release of other proinflammatory cytokines, such as IL-6, IL-8, platelet-activating factor, complement, thromboxanes, leukotrienes, prostaglandins, NO, and others.[104]

The presence of these cytokines promotes inflammation and vascular endothelial injury, but it also causes an overwhelming activation in coagulation. Thrombin has potent proinflammatory and procoagulant activities, and its production is increased in sepsis. The human body normally counteracts these effects by increasing fibrinolysis, but the homeostatic mechanisms in the patient with sepsis are dysfunctional. There are decreases in the levels of protein C, plasminogen, and antithrombin III as well as increased activity of plasminogen activator inhibitor-1 and thrombin-activatable fibrinolysis inhibitor, endogenous agents that inhibit fibrinolysis.[105] The patient is in a coagulopathic state, which promotes formation of microvascular thrombi, leading to hypoperfusion, ischemia, and, ultimately, organ failure. Multiple organ failure is responsible for about half the deaths caused by septic shock.[106]

The clinical features of sepsis are highly variable and depend on multiple factors: site of infection, causative organism, degree of organ dysfunction, baseline patient health status, and delay to initial

treatment.[107] The working definition of sepsis accounts for the presence of systemic manifestations of infection and organ dysfunction, which may be subtle (Table 17-8). Serum biomarkers are the subject of intense research because they could aid the early diagnosis of sepsis, guide treatment, and predict outcomes. Most biomarkers have not been extensively studied and few are in clinical use (eg, C-reactive protein, procalcitonin, soluble triggering receptor expressed on myeloid cells 1 [sTREM-1], CD64, pancreatic stone protein).[108] Most of these biomarkers have high negative predictive values, but lack high specificity and positive predictive value.

Characteristic laboratory findings include leukocytosis or leukopenia, thrombocytopenia with or without coagulation abnormalities, and, often, hyperbilirubinemia. These features are usually readily detectable and occur within 24 hours of sepsis developing. In extremes of age (very young or very old) or in debilitated patients, hypothermia can be present, and positive findings may be limited to unexplained hypotension, mental confusion, and hyperventilation.

Persons dying of septic shock often have a normal or elevated CO. Death within the first week of the onset of sepsis occurs as a result of intractable hypotension that is secondary to significantly depressed SVR. This causes extensive maldistribution of blood flow in the microvasculature, with subsequent tissue hypoxia and development of lactic acidosis. Death occurring beyond the first week usually is caused by multiple organ failure that began during acute circulatory failure. Severe, unresponsive hypotension as a result of a decreased CO occurs in a subpopulation of patients with septic shock; cardiogenic shock becomes superimposed on the distributive shock of sepsis, but this is a less common cause of death.[109]

Clinical and Hemodynamic Features

CASE 17-4

Question 1: E.B., a 71-year-old female, presents to the ICU with hypoxemic respiratory failure after a 4-day stay on the floor. She initially presented from home with altered mental status and a urinary tract infection that was being managed on the floor with ceftriaxone.

E.B. has a history of diabetes mellitus type 2, hypertension, chronic kidney disease stage II, dyslipidemia, coronary artery disease, obesity, and peripheral arterial disease.

Physical findings include a temperature of 101.66 °F (38.7 °C), BP 95/60 mm Hg, pulse 120 beats/min, and RR 32 breaths/min with oxygen saturation 88% on 2 L/min nasal cannula. E.B. weighs 224.87 pounds (102 kg) and is 65 inches (165.01 cm) tall. A Foley catheter is placed in her bladder and her urine output is 0.4 mL/kg/hour. The chest radiograph shows bilateral patchy opacities.

Pertinent laboratory values are as follows:

WBC count, 19,500 cells/mL
BUN, 58 mg/dL
SCr, 2.2 mg/dL
Na, 131 mEq/L
Glucose, 58 mg/dL
Albumin, 1.6 g/dL
Lactate, 4.5 g/dL

ABG measurements on 2 L/min nasal cannula (FiO_2 27%) are as follows:

PaO_2, 56 mm Hg
$PaCO_2$, 32 mm Hg
HCO_3^-, 16 mEq/L
pH, 7.31

Urine, sputum, and blood samples are sent for culture and sensitivity. A fluid bolus of 1000 mL of LR is given. An arterial pressure line was inserted, revealing the following hemodynamic profile:

BP (S/D/M), 90/48/62 mm Hg
HR, 122 beats/min

What hemodynamic and clinical features of E.B. are consistent with septic shock?

E.B. would not be classified in septic shock at this time because she has not been adequately fluid resuscitated. However, she would be classified as having sepsis because of the manifestations of infection and organ dysfunction.

E.B. has a metabolic acidosis (pH 7.31, $Paco_2$ 32 mm Hg, HCO_3^- 16 mEq/L), indicating anaerobic metabolism and lactic acidosis most likely caused by decreased perfusion, and a CO that is inadequate to meet the oxygen requirements of the tissues. Other features consistent with sepsis in E.B. include declining urine output indicating decreased renal perfusion, hypoglycemia, a rising WBC count, and a spiking fever.

Therapeutic Approach

The management of septic shock is directed toward three primary areas: (a) eradication of the source of infection, (b) hemodynamic support and control of tissue hypoxia, and (c) inhibition or attenuation of the initiators and mediators of sepsis.

ERADICATING THE SOURCE OF INFECTION

Case 17-4, Question 2: What factors should be considered in determining antimicrobial therapy in septic shock? What are the potential sources of infection in E.B.?

Systemic infection caused by either aerobic or anaerobic bacteria is the leading cause of septic shock. Fungal, mycobacterial, rickettsial, protozoal, or viral infections can also be encountered. The source of infection (ie, respiratory, intra-abdominal, genitourinary, skin/soft tissue infection) helps determine which bacteria are of concern and therefore should be empirically covered.

Eradicating the source of infection involves the early administration of antimicrobial therapy, and source control, if indicated. Antimicrobials should be administered within 1 hour of recognition for patients with septic shock or who have a high likelihood of sepsis. For patients with possible sepsis without shock, rapid assessment of non- infectious causes should occur. If concern for infection still exists after rapid investigation of other causes, antimicrobials should be administered within 3 hours of sepsis

recognition.[4] The use of an appropriate antibiotic regimen within 1 hour of diagnosis of septic shock is associated with a significant increase in survival.[110] Appropriate cultures should be obtained before starting antibiotic therapy, unless this would result in a significant (>45 minutes) delay in therapy.[4] The selection of antibiotics should take into account the presumed site of infection; whether the infection is a community associated or health care–associated one; recent invasive procedures, manipulations, or surgery; any predisposing conditions; drug intolerances; and the likelihood of drug resistance. Ideally, the primary source of infection can be determined and therapy specifically tailored to the most likely organisms. If the source of infection is unclear, however, early institution of broad-spectrum antibiotics against all likely pathogens is generally recommended while awaiting culture results. Empiric broad- spectrum therapy usually requires combinations of antimicrobials because of the increasing frequency of polymicrobial infections and antimicrobial resistance. Mortality for septic shock may be as much as fivefold higher when an empiric regimen fails to cover the offending pathogen.[4] Every hour of delay of appropriate antibiotics may lead to a 7.6% decrease in survival.[110] Because a wide range of variables must be considered in the selection of empiric regimens (eg, anatomic site of infection, pathogen prevalence, resistance patterns), a specific regimen cannot be recommended for all episodes of sepsis or septic shock (see Chapter 62, Principles of Infectious Diseases). Generally, empiric regimens target gram-positive cocci, aerobic gram-negative bacilli, as well as anaerobes and include (a) an antipseudomonal penicillin, fourth-generation cephalosporin, or carbapenem plus (b) vancomycin to cover methicillin-resistant *Staphylococcus aureus* (MRSA) for high risk patients. Combination gram-negative coverage (eg, aminoglycoside, fluoroquinolone) is recommended for critically ill patients at risk of infection with difficult-to-treat, multidrug-resistant pathogens, such as *Pseudomonas* and *Acinetobacter* spp. Additional coverage should be considered based on the presence of other risk factors (eg, *Candida* species, atypical pathogens, viremia).

The most likely potential source of sepsis in E.B. is hospital-acquired pneumonia. Other sources of infection are less likely based on her presentation. For patients with hospital-acquired pneumonia, empiric antimicrobials should cover *Pseudomonas aeruginosa*, other gram-negative bacilli, and *S. aureus*. Patients with risk factors for MRSA (ie, prior IV antibiotic use within 90 days, hospitalization in a unit with >20% or unknown rate of MRSA isolates, or high risk of mortality) should be empirically covered for MRSA. The team has chosen to start cefepime and vancomycin. Antimicrobial therapy should be adjusted once cultures are finalized.

CASE 17-4, QUESTION 3: What are the immediate goals of therapy in E.B.? How can they be achieved and assessed?

INITIAL STABILIZATION

The goals in treating septic shock, in addition to eradicating the precipitating infection, are to optimize $\dot{D}o_2$ to the tissues and to control abnormal use of oxygen and anaerobic metabolism by reducing the tissue oxygen demand. Tissue injury is widespread during sepsis, most likely because of vascular endothelial injury with fluid extravasation and microthromboses, which decrease oxygen and substrate utilization by the affected tissues. The mainstay of therapy is volume expansion to increase intravascular volume, enhance CO, and ultimately delay associated development of refractory tissue hypoxia.

Increasing CO with fluids will improve capillary circulation and tissue oxygenation by maintaining sufficient intravascular volume. Current guidelines suggest a fluid bolus of 30 mL/kg of IV crystalloid fluid should be given within the first 3 hours of resuscitation.[4] If fluids do not correct the hypoxia or if filling pressures are increased, the sequential addition of vasopressors and inotropic agents is indicated. Crystalloids should be initiated to maintain a MAP of >65 mm Hg. Balanced crystalloids are recommended over NS.[45] Although MAP is not an absolute measure of blood flow to all vital organs, it is considered the therapeutic end point that will sustain myocardial and

cerebral perfusion. After optimization with fluid therapy, vasopressor and inotropic agents are indicated if the patient remains hypotensive with a low CI or if signs of inadequate tissue perfusion persist.

The therapeutic goals used for hemodynamic resuscitation are controversial. The issue is whether therapy should be directed to physiologic end points of tissue perfusion or clinical end points, such as BP and urine output. The physiologic end points include clearance of blood lactate concentrations, base deficit, Svo_2, and increased CO. Serum lactate concentrations may be elevated through various mechanisms (eg, tissue hypoxia, excessive β-adrenergic stimulation, liver failure), but are associated with worse outcomes regardless of the source. Dynamic measures of volume responsiveness such as passive leg raise, stroke volume, stroke volume variation, pulse pressure variation, or echocardiography are suggested. Resuscitation can also be guided by decreasing serum lactate and capillary refill time. Lactate-guided resuscitation of patients in septic shock is recommended because of its association with a significantly reduced mortality rate compared with usual care.[4]

Many institutions have developed “sepsis bundles” that incorporate these same variables and therapeutic end points as early as possible in the treatment of sepsis. Sepsis bundles often include many additional issues addressed in the Surviving Sepsis Campaign Guidelines, such as ventilatory support, initial choice of antibiotics, glucose control, and stress ulcer prophylaxis.[4]

One study by Rivers et al. combined physiologic and clinical end points of resuscitation during the early stages of sepsis.[111] CVP, MAP, Hct, and $Scvo_2$ were optimized during at least 6 hours of continuous care in the ED. This was compared to conventional therapy that targeted only CVP, MAP, and urine output. In-hospital mortality was significantly lower in the early goal-directed therapy (EGDT) group (30.5% vs 46.5%, $P = .009$). EGDT was adopted as the standard of care in the treatment of sepsis and septic shock. However, there are several limitations to the EGDT approach. As noted earlier, CVP is an unpredictable marker of fluid resuscitation, and fluid overload is common after EGDT resuscitation.[58]

Furthermore, the Hct target of 30% is unnecessarily high because transfusions of PRBCs to achieve an Hgb >7 g/dL do not increase $ScvO_2$. Finally, the use of invasive monitoring with PACs has fallen out of favor because they do not improve mortality in critically ill patients and the derived data is often incorrectly measured and/or interpreted.[112]

Several large, multicenter studies have shown no improvement in patient outcomes using EGDT for severe sepsis and septic shock. Protocol-based resuscitation did not improve in-hospital mortality among 1341 patients in the ProCESS (*Protocolized Care for Early Septic Shock*) study.[113] In the ARISE (Australasian Resuscitation In Sepsis Evaluation) and ProMISe (*Pro*tocolized *M*anagement *I*n *Se*psis) studies, EGDT did not reduce all-cause mortality compared to usual care.[114,115] The mortality rates among the usual care groups from these trials (18.9%,[113] 18.8%,[114] 29.2%[115]) were similar to that of the EGDT group in the Rivers et al study. These findings could be because of an improvement in our standard of care over that time period, chiefly the early identification and treatment. Nonetheless, the most recent Surviving Sepsis Campaign Guidelines have departed from the EGDT-guided resuscitation strategy from the Rivers study.[4]

E.B. should receive fluid boluses to maintain perfusion with a MAP of at least 65 mm Hg. Reassessment of E.B.'s hemodynamic status should include a thorough clinical examination as well as assessment of available physiologic variables (eg, HR, BP, SaO_2, RR, temperature, urine output). A bolus of 30 mL/kg crystalloid fluid challenge is recommended within the first 3 hours of resuscitation. Albumin may be substituted if large volumes of crystalloids are required, but HESs should be avoided because of an increased risk of acute renal dysfunction and potential increased mortality.[4] Excessive volume administration should be avoided because substantial data have linked fluid overload with worse outcomes including acute kidney injury, days in organ failure, and mortality. This has led many investigators to study early fluid minimization strategies. Further fluid administration should be done cautiously.

The optimal amount of fluid administration is still being investigated in the Crystalloid Liberal or Vasopressors Early Resuscitation in Sepsis (CLOVERS) studies.[116]

In summary, the immediate goal of therapy is to maximize $\dot{D}o_2$ to the tissues. Early, but judicious, fluid resuscitation is the mainstay of therapy and improves $\dot{D}o_2$ by increasing CO; however, vasopressor agents are often required for additional cardiovascular support. A favorable response to immediate resuscitative efforts will be reflected by a reversal or halt in the progression of the metabolic acidosis, improved sensorium, and increased urine output. In E.B., selection of appropriate antibiotics while maintaining hemodynamic support are the clinical goals of therapy.

HEMODYNAMIC MANAGEMENT

Fluid therapy versus inotropic support

Case 17-4, Question 4: E.B. is given three 1000-mL fluid boluses, and norepinephrine is begun at a rate of 0.05 µg/kg/min. During the next 2 hours, she receives 4 L of fluid in boluses, and the norepinephrine is increased to 0.3 µg/kg/min to maintain her BP. She does not have signs of pulmonary edema on chest x-ray and her Spo_2 remains 96%. E.B. has the following hemodynamic profile (previous values in parentheses):

BP (S/D/M), 95/48/64 mm Hg (90/48/62 mm Hg)
HR, 124 beats/min (122 beats/min)
Urine output, 0.25 mL/kg/hour (0.4 mL/kg/hour)
Pao_2, 85 mm Hg (98 mm Hg)
$Paco_2$, 36 mm Hg (32 mm Hg)
HCO_3^-, 17 mEq/L (16 mEq/L)
pH, 7.3 (7.31)

Bedside ultrasound reveals a noncollapsible IVC that is 2.5 cm in diameter. Which of the following therapeutic considerations would be reasonable for E.B. at this time: additional fluid boluses, an increase in the norepinephrine infusion rate, or initiation of a different vasopressor?

E.B. continues to be hypotensive despite volume resuscitation and a norepinephrine infusion rate of 0.3 μg/kg/min. Her IVC is plump, suggesting adequate volume resuscitation. The goals of therapy remain the same (ie, maximize arterial oxygen content and $\dot{D}o_2$ to reverse cellular anaerobic metabolism).

E.B.'s PaO_2 of 85 mm Hg correlates with an oxygen–hemoglobin saturation of ~96%, which should provide adequate arterial oxygen content. However, $\dot{D}o_2$ still may be inadequate. E.B.'s Hgb and Hct should be checked to ensure adequate oxygen-carrying capacity in the blood. In addition, decreased tissue oxygen utilization can contribute to the continued acidosis. Further attempts to enhance the CI and, hence, $\dot{D}o_2$ are appropriate. E.B. has a dilated heart and a history of cardiovascular disease and chronic kidney disease that will influence the choice of therapeutic options.

Although fluid administration is the mainstay of therapy in septic shock, the increased IVC diameter suggests that E.B. has been adequately volume resuscitated. Therefore, additional fluid therapy to maintain BP may cause pulmonary edema, compromise pulmonary gas exchange, and increase the risk of other complications such as acute kidney injury. Additional fluid boluses at this time should be used only to maintain the current level of intravascular volume status.

VASOPRESSORS AND INOTROPIC AGENTS

When fluid therapy fails to maintain a satisfactory MAP despite an elevated CO, the use of a vasopressor should be considered. The optimal time to initiate vasopressors is still being investigated.[116] It is now suggested to start vasopressors peripherally rather than delay initiation until central venous access is established.[4] Maintaining a goal MAP does not correlate with decreased mortality, but it helps sustain myocardial and cerebral perfusion. If it is necessary to increase CO, then inotropic agents should be used. Although the use of inotropic agents is well established, controlled comparative studies have not clearly determined which agent, or combination of agents, is most useful in the management of septic shock. Because

differences among the inotropic agents are significant, however, selection of the most appropriate drug should be guided by careful consideration of the patient's hemodynamic status. A recent observational trial hypothesized that early aggressive vasopressor titration may be preferred over low-dose initiation and slow uptitration. The investigators also suggest that a more aggressive vasopressor starting dose must also be accompanied by early and adequate volume resuscitation to prevent deleterious effects of high-dose vasopressors.[117]

Norepinephrine

Norepinephrine is predominantly an α-adrenergic agonist (Table 17-7) and is the recommended first-line vasopressor for sepsis.[4] Norepinephrine has been titrated to 0.3 μg/kg/min, but E.B.'s HR will likely limit the utility of further increases in the dose.

Vasopressin

Catecholamines have been the mainstay of treatment to support BP in patients with sepsis once adequate fluid resuscitation has been achieved. Sepsis, however, can cause a decrease in responsiveness to catecholamines, resulting in refractory hypotension, possibly because of downregulation of adrenergic receptors or altered receptor relative binding affinities in hypoxic and acidotic conditions.[82] Vasopressin is an endogenous hormone that has very little effect on BP under normal conditions, but it becomes important in maintaining BP when the baroreceptor reflex is impaired. In contrast to the catecholamines, vasopressin's effects are relatively preserved in hypoxic and acidotic states.[82] For adult patients with septic shock with inadequate MAP response to norepinephrine alone, current guidelines suggest adding vasopressin instead of increasing doses of norepinephrine.[4] The optimal dose of norepinephrine for vasopressin initiation is not yet established.

Vasopressin's direct vasoconstricting actions are mediated by the vascular V_{1a} receptors coupled with phospholipase C.[82,120] When these receptors are activated, calcium is released from the

sarcoplasmic reticulum in smooth muscle cells, leading to vasoconstriction. Vasopressin levels peak in early septic shock and decrease to low-normal levels in most patients within 48 hours. This phenomenon is called a *relative vasopressin deficiency* because higher vasopressin levels would be expected in hypotensive states.

The VASST (Vasopressin And Septic Shock Trial) study compared norepinephrine monotherapy to norepinephrine plus vasopressin in patients with septic shock, who were unresponsive to fluids and assessed mortality at 28 days.[121] Vasopressin significantly decreased the amount of norepinephrine required; however, there was no difference in mortality between the treatment groups except when the patients were stratified according to severity of sepsis. The patients with less severe septic shock benefited from vasopressin therapy. The VAsopressin vs Noradrenaline as Initial therapy in Septic sHock (VANISH) trial compared early vasopressin to norepinephrine and again found that vasopressin reduces catecholamine requirements. The study also found that fewer patients in the vasopressin group required renal replacement therapy, but this was mostly in nonsurvivors. There was no difference in renal replacement therapy–free days or mortality.[122]

Low-dose vasopressin (up to 0.03 units/min) is recommended to synergistically achieve the goal MAP with norepinephrine or allow norepinephrine dose reductions.[4] Doses >0.03 to 0.04 units/min are only recommended as salvage therapy.[4]

E.B. has a decreased MAP despite the increased titration of norepinephrine. The optimal time to consider additional or alternative therapies to norepinephrine is unknown. Because patients in septic shock have decreased endogenous levels of vasopressin, it would be reasonable to add vasopressin at 0.03 units/min to increase the MAP and renal perfusion.

Epinephrine

Epinephrine stimulates α-, β_1-, and β_2-adrenergic receptors (Table 17-7). CO is augmented via increased contractility and HR, with the contribution of each being highly variable. Blood vessels in the

kidney, skin, and mucosa constrict in response to α-adrenergic stimulation, whereas vessels in the skeletal muscle vasodilate because of β_2 effects. A biphasic response in SVR is observed as β_2-receptors are activated at the lower range and α_1-receptors are stimulated at higher infusion rates. The improvement in CO, therefore, may be negated by an increase in afterload at higher dosages.

Historically, epinephrine was reserved as a last-line therapy because of the studies that showed harmful splanchnic and renal vasculature effects and elevated lactate levels. Despite these effects, there are no clinical studies showing that epinephrine causes worse outcomes in sepsis. In fact, two prospective, double-blind, randomized controlled trials comparing epinephrine and norepinephrine in patients with septic shock found similar mortality rates, time to hemodynamic recovery, and time to vasopressor withdrawal.[118,119] Both studies showed lower arterial pH values associated with impaired serum lactate clearance in the epinephrine-treated groups. Therefore, lactate clearance would not be recommended to guide resuscitation when utilizing epinephrine.

Epinephrine is recommended as adjunctive therapy to norepinephrine and vasopressin to maintain adequate MAP.[4] However, if tachyarrhythmias are limiting the use or norepinephrine, epinephrine is likely to produce similar effects because it also stimulates β_1-receptors. Consequently, it is not appropriate to substitute epinephrine for norepinephrine at this time for E.B.

Dopamine

Dopamine previously was another initial pharmacologic agent chosen for the treatment of septic shock. A trial that randomized 1679 patients with shock to dopamine or norepinephrine for BP support found no significant difference in the primary outcome of 28-day mortality, but there was an increased risk of arrhythmic events with dopamine.[83] A meta-analysis of six randomized trials of patients with sepsis found that dopamine was associated with an increased risk of death and arrhythmias compared to norepinephrine.[123]

Similarly, another meta-analysis that included six randomized trials found norepinephrine was associated with a lower in-hospital and 28-day mortality compared to dopamine as well as a lower incidence of arrhythmias.[124]

In light of these findings, the Surviving Sepsis Campaign relegated dopamine from a first line to an alternative vasopressor. Dopamine is now reserved for patients with absolute or relative bradycardia and a low risk of tachyarrhythmias, which is difficult to predict.[4] Accordingly, dopamine is not an appropriate therapeutic option for E.B.

In addition, low-dose dopamine should not be used for renal protective purposes.[4] Dopamine does not decrease the time to recovery of renal function or the need for renal replacement therapy.

Phenylephrine

Phenylephrine is a pure α-adrenergic agonist (Table 17-7) and, thus, increases systolic, diastolic, and MAPs through vasoconstriction. Reflex bradycardia can occur secondarily because of the absence of β-adrenergic effects. The increase in afterload, while increasing myocardial $\dot{V}o_2$, correspondingly increases coronary blood flow because of increased perfusion pressure and autoregulation. In patients with myocardial hypoxia, or in those experiencing atrial or ventricular arrhythmias, phenylephrine can be beneficial because it has minimal direct cardiac effects. In situations in which the CO is decreased, phenylephrine can be detrimental. Preload is reduced because plasma fluid is lost owing to increased capillary hydrostatic pressure, forcing water and solutes from the vascular space into the interstitial spaces. This response, in addition to the increased afterload and reflex bradycardia, may significantly impair CO (Table 17-7). Therefore, phenylephrine should be reserved for treating septic shock in the following patients: (a) those with arrhythmias on norepinephrine, (b) those with high CO but persistent hypotension, or (c) those who fail to achieve the goal MAP on combination inotropes/vasopressors and low-dose vasopressin. Phenylephrine is a reasonable alternative therapy for E.B. if her hypotension and tachycardia persist despite the addition of vasopressin.

Angiotensin II

Angiotensin II is a synthetic octapeptide identical to endogenous human angiotensin II that can improve BP in patients with catecholamine- resistant distributive shock. It was approved by the U.S. Food and Drug Administration (FDA) based on the results of the Angiotensin II for the Treatment of High-Output Shock 3 (ATHOS-3) trial, which showed a significant increase in MAP response at 3 hours compared to placebo.[125] Patients in the angiotensin II group experienced venous thromboembolism (VTE) at a higher rate than patients on placebo. Because of the increased risk of VTE, the package insert recommends ensuring that patients are on appropriate VTE prophylaxis before administration.[126] The clinical application and place in therapy of angiotensin II have not yet been fully established. Currently, routine use is cost prohibitive.

Dobutamine

Tissue $\dot{D}o_2$ may be impaired by a suboptimal CO or decreased oxygen-carrying capacity. If tissue hypoperfusion persists after optimizing fluid status, achieving the goal MAP, and assuring an adequate Hgb concentration, then CO should be assessed. Epinephrine and dopamine are inotropic therapies with vasoconstricting properties, but dobutamine is the recommended first-line inotropic agent in the management of septic shock.[4] Dobutamine produces a greater increase in CO than does dopamine, but it also lowers SVR. In contrast to dopamine, dobutamine lowers PCWP and causes less pulmonary shunting. Because dobutamine can lower ventricular filling pressure, volume status must be monitored closely to avoid the development of hypotension and reduced MAP. Fluids should be administered as needed to maintain the PCWP at optimal and tolerated levels of 15 to 18 mm Hg. With the administration of greater amounts of fluid, CO, $\dot{D}o_2$, and systemic $\dot{V}O_2$ are significantly increased. Dobutamine increases $\dot{D}o_2$ and CI when given concurrently with or after volume resuscitation, and it may independently increase capillary perfusion regardless of systemic effects. Decreases in PaO_2 and increases in

venous P_{O_2}, as well as adverse effects on myocardium, may be evident at higher dosages (>6 μg/kg/min).[127]

Combinations of vasopressors and inotropic agents can also be used to achieve desired hemodynamic parameters. GI perfusion can be compromised owing to the vasoconstricting effects of catecholamines and may play a role in the pathogenesis of multiple organ dysfunction.[88] Currently, it is unknown whether a specific catecholamine regimen provides a significant benefit over others. There are conflicting data about which vasopressor can increase gastric perfusion and whether this increase can alter progression to organ dysfunction.

CASE 17-4, QUESTION 5: Given E.B.'s history of cardiovascular disease, what factors should you consider before initiating an inotropic or alternative vasopressor agent? Outline an overall approach to maintaining adequate hemodynamic status.

E.B. has a history of coronary artery disease and is susceptible to myocardial ischemia. Therefore, a careful balance must be achieved between myocardial $\dot{V}O_2$ and coronary perfusion pressure. Further attempts to optimize MAP and CI with norepinephrine alone could increase myocardial $\dot{V}O_2$ and precipitate ischemia. Evidence suggests that the goal of therapy in treating patients with septic shock, or any form of shock for that matter, is not to simply normalize BP but to optimize $\dot{D}O_2$ and $\dot{V}O_2$. Once anemia and hypoxia have been corrected, CO becomes the remaining parameter that can be adjusted to increase oxygen supply, but raising arterial BP and CO with inotropic agents or vasopressors before restoring adequate blood volume can actually worsen tissue perfusion. Therefore, the patient's current hemodynamic status and the individual properties of those agents that will most effectively maintain or increase the MAP and CO should be considered while selecting an inotropic agent. In many instances, because of individual variability and response, more than one inotropic agent or addition of a vasopressor is required to achieve these end points. These interventions must be made with strict monitoring of the patients' response to the interventions to

prevent any adverse consequences, especially in those patients who are predisposed to an adverse event, such as E.B.

It is important to realize that the response to exogenous catecholamines in patients with septic shock is highly variable, and a successful regimen in one patient may be unsuccessful in another. In addition, patients with sepsis often require infusion rates in the moderate-to-high range. Therefore, the goal is to use one or more agents at the dosages necessary to achieve the desired end points without unduly compromising the patient's status. The use of catecholamines, however, is only a stabilizing measure. Strict attention to all other physiologic parameters—as well as nutritional support, antibiotic modification, respiratory support, and ongoing surgical intervention—cannot be overemphasized.

CORTICOSTEROIDS

Case 17-4, Question 6: What is the rationale for the use of glucocorticoids in the treatment of septic shock, and is there evidence to support their use for this indication in E.B.?

The use of corticosteroids in sepsis and septic shock has been a controversial topic for many years. Corticosteroids were originally proposed as a treatment option because of their anti-inflammatory properties, with the hope of attenuating the body's response to infection. It has been shown that critically ill patients exhibit impaired cortisol secretion because of a relative adrenocortical insufficiency and a glucocorticoid peripheral resistance syndrome that can also be affected by multiple medications.[128] The Consensus Task Force from the Society of Critical Care Medicine and European Society of Intensive Care Medicine has defined this dysfunction of the hypothalamic–pituitary–adrenal axis as *critical illness–related corticosteroid insufficiency*.[129,130]

Diagnosis of this condition is intensely debated. Some clinicians recommend a random cortisol level that is below a certain threshold during physiologic stress (ie, shock) to diagnose adrenal

insufficiency; however, this has only been shown to be useful in diagnosing absolute adrenal insufficiency.[4] The traditional assessment method has been the adrenal corticotropin hormone (ACTH) stimulation test with administration of either 1 or 250 μg of cosyntropin. However, the ACTH test only evaluates the adrenal function, not the entire hypothalamic–pituitary–adrenal axis, and lacks sensitivity and specificity in critical illness.[128] Random cortisol levels may be useful for evaluating absolute adrenal insufficiency, but have not demonstrated a benefit in patients with septic shock. The Surviving Sepsis Campaign does not recommend the ACTH stimulation test or random cortisol levels to identify patients who should receive glucocorticoids.[4]

Clinical trials investigating the use of steroids in septic shock have been performed with varying results with respect to mortality. The trial by Annane et al. showed a shortened time to shock reversal and mortality benefit with the use of low doses of hydrocortisone and fludrocortisone in patients with severe septic shock, who exhibited a relative adrenocortical insufficiency (serum cortisol increase ≤9 μg/dL in response to ACTH stimulation).[131] The Corticosteroid Therapy of Septic Shock (CORTICUS) trial showed a faster resolution of shock for those patients on hydrocortisone, as evidenced by faster time to weaning from vasopressors; however, those patients also had a higher incidence of superinfection and new episodes of sepsis or septic shock.[132] There was no mortality benefit seen with the use of corticosteroids. The CORTICUS trial included patients with septic shock, whereas the study by Annane et al. only enrolled patients with severe septic shock unresponsive to vasopressor therapy. The HYPRESS (*Hy*drocortisone for *Pre*vention of *S*eptic *S*hock) trial randomized patients with severe sepsis and those who had not progressed to shock to hydrocortisone 200 mg/day versus placebo.[133] There was no difference in progression to shock or 28-day mortality. Patients in the hydrocortisone group experienced more hyperglycemia. Two large randomized controlled trials of over 5000 critically ill patients with sepsis were recently published and add to the clinical evidence. The ADjunctive coRticosteroid trEatment iN criticAlly ilL Patients With Septic Shock

(ADRENAL) trial randomized 3658 patients with septic shock requiring mechanical ventilation for <24 hours to receive hydrocortisone 200 mg/day or placebo.[134] There was no difference in the primary end point of 90-day mortality. Hydrocortisone was associated with reduced duration of shock, reduced duration of mechanical ventilation, and reduced ICU length of stay. The APROCCHSS (*A*ctivated *Pro*tein *C* and *C*orticosteroids for *H*uman *S*eptic *S*hock) trial randomized 1241 patients with septic shock to hydrocortisone IV 50 mg every 6 hours and fludrocortisone 50 μg orally daily versus placebo for 7 days.[135] The hydrocortisone and fludrocortisone group had lower 90-day mortality but not 28-day mortality. Vasopressor-free days at 28 days were also higher in the treatment group. It is not clear why the results of ADRENAL and APROCCHSS differ. APROCCHSS enrolled much sicker patients with a higher mortality. The results of these studies demonstrate that corticosteroid therapy likely has a small benefit of decreased mortality in patients with septic shock, particularly if more severe.[136] Adverse effects (ie, hypernatremia, hyperglycemia, increased risk of neuromuscular weakness) are likely minimal with short-term corticosteroid use in this population. Thus, corticosteroids may be a reasonable choice for those patients unresponsive to vasopressors.

The optimal dose, duration, and method of administration are still unknown. The Surviving Sepsis Campaign recommends hydrocortisone 200 mg/day.[4] Continuous infusion of hydrocortisone may avoid significant fluctuations in glucose and sodium. Because E.B. is refractory to increasing doses of norepinephrine and requires additional vasopressor support, it was decided to start hydrocortisone 50 mg IV every 6 hours.

Ascorbic acid and thiamine

Interest in hydrocortisone, ascorbic acid (vitamin C) and thiamine (HAT) as separate agents and in combination with hydrocortisone have been receiving significant attention in recent years as adjunctive therapies in multiple subpopulations of septic shock. Vitamin C is important for cellular regulation and immune system

function. Vitamin C is an essential cofactor for endogenous catecholamine and vasopressin synthesis, and is known to be depleted in critically ill patients because of consumption and reduced intake.[137] In a phase I trial, vitamin C decreased SOFA score in a dose-dependent manner.[138] Thiamine is the precursor of thiamine pyrophosphate, which is an essential component of the Krebs cycle. Serum thiamine concentrations are reduced in 20% of patients with sepsis because of increased metabolic consumption and decreased intake.[139] Thiamine has been shown to improve lactate clearance.[140,141]

The role of vitamin C and thiamine in sepsis has been evaluated in observational and randomized control trials. A retrospective before–after trial evaluated 94 patients who received vitamin C within 24 hours of ICU admission and showed a decrease in duration of vasopressors and hospital mortality in patients treated with HAT.[142] Randomized controlled trials have produced inconsistent results. The Vitamin C, Hydrocortisone and Thiamine in Patients With Septic Shoc (VITAMINS) trial, the largest randomized control trial to evaluate the use of HAT therapy, evaluated the effects of HAT therapy (*N* = 109) versus hydrocortisone (*N* = 107). The study reported no difference in median time alive and vasopressor-free days up to day 7, hospital mortality, ICU mortality, 28-day mortality, or 90-day mortality.[143] HYVCTTSSS (*Hy*drocortisone, *V*itamin *C*, and *T*hiamine combination *T*reatment for patients with *S*epsis or *S*eptic *S*hock) showed a decrease in 72-hour SOFA score in patients who received HAT.[144] In Outcomes of metabolic Resuscitation using Ascorbic acid, thiamiNe, and Glucocorticoids in the Early treatment of Sepsis (ORANGES), patients who received HAT had faster resolution of shock, defined as time to vasopressor discontinuation.[145] Neither HYVCTTSSS nor ORANGES found a difference in mortality.[144,145]

There is inconsistency in the vitamin C dosing regimens used in clinical trials, making it challenging to draw definitive conclusions on its role in sepsis. The most common doses used in clinical trials are IV ascorbic acid 1500 mg every 6 hours and thiamine 200 mg every 12 hours. In general, vitamin C appears to be safe. However,

patients should be monitored for nephropathy and glucose monitoring errors when high-dose vitamin C is administered. Thiamine also appears to be safe. Overall, there is insufficient evidence to support the routine use of vitamin C and thiamine in sepsis. Current guidelines suggest against the use of IV vitamin C for septic shock.[4]

Asthma

Cary R. Chrisman and Christopher K. Finch

CORE PRINCIPLES		CHAPTER CASES
1	Asthma is a heterogeneous disease usually characterized by chronic airway inflammation that is defined by the Global Initiative for Asthma as history of respiratory symptoms such as wheeze, shortness of breath, chest tightness, and cough that vary over time and in intensity, together with variable expiratory airflow limitation.[1]	**Case 18-1 (Question 1)** **Case 18-2 (Question 1)** **Case 18-6 (Question 1)** **Case 18-7 (Question 1)**
2	There are a variety of phenotypes, and now endotypes, used to further categorize the etiology and treatment of asthma, which allows for a more personalized approach to treatment than in the past.	**Case 18-3 (Question 1)** **Case 18-6 (Question 1)** **Case 18-7 (Question 1)**
3	The clinical presentation of asthma	**Case 18-3 (Question 1)**

	includes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and in the early morning. These episodes are usually associated with widespread, but variable, airflow obstruction that is often reversible either spontaneously or with treatment.	**Case 18-4 (Question 1)** **Case 18-5 (Question 1)** **Case 18-7 (Question 1)** **Case 18-8 (Question 1)**
4	Core management principles include environmental control, inhaled corticosteroid (ICS) maintenance therapy, simultaneous utilization of ICS whenever a β-agonist is administered, biologic treatment for the most severe asthma, and management of comorbidities that worsen asthma.	**Case 18-6 (Question 1)** **Case 18-7 (Question 1)** **Case 18-8 (Questions 1, 2)** **Case 18-9 (Question 1)**

INTRODUCTION

Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role (**Fig. 18-1**). Airway inflammation also causes an increase in the existing bronchial hyperresponsiveness to a variety of stimuli. Bronchospasm is another key feature of asthma.[2] In susceptible persons, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and in the early morning. These episodes are usually associated with widespread, but variable, airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an increase in the existing bronchial hyperresponsiveness to a variety of stimuli.[2] In 2019, and estimated 25.1 million Americans

carried a diagnosis of asthma, a prevalence of approximately 7.8%.[3] It is an underdiagnosed and undertreated condition that is estimated to have overall costs of roughly $80 billion annually in the United States.[4] Asthma was the cause of 1.6 million emergency department (ED) visits in 2017, is one of the leading causes of lost school days in children, and is a common cause of lost workdays among adults.[2,3] Mortality from asthma has decreased in the 21st century, from 4657 (1.7 per 100,000) deaths in 1999 to 3441 (1.1 per 100,000) deaths in 2018, but has been largely stable since 2011 in the United States, according to the Centers for Disease Control and Prevention.[5] However, morbidity and mortality are still unacceptably high, especially in inner-city minority populations. This chapter emphasizes the Global Initiative for Asthma (GINA) 2020,[1] National Institutes of Health (NIH) Expert Panel Report (EPR-3)[2] including the 2020 focused updates, and European Respiratory Society/American Thoracic Society (ERS/ATS) guidelines. Application of the principles of these guidelines by clinicians and patients is vital to further reducing asthma morbidity and mortality.

Etiology

PHENOTYPIC PRESENTATIONS

Asthma is a heterogeneous disease categorized into one of several phenotypes, which is particularly important in the workup of poorly controlled asthma. However, a given patient may have more than one phenotypic presentation (see Fig. 18-1).[1]

The most common phenotype, termed *allergic* asthma, is most often found to involve eosinophilic and immunoglobulin E (IgE)-associated inflammation, and typically responds well to inhaled

corticosteroids (ICSs).[1,6] This includes the majority of childhood-onset disease, and is usually associated with atopy, which is the genetic predisposition for the development of IgE-mediated response to common aeroallergens. Atopy is the strongest predisposing factor in the development of asthma.[2] A very common presentation of asthma is a child with a positive family history of asthma and allergy to tree and grass pollen, house dust mites, household pets, and molds.

Nonallergic asthma is a less common phenotype, where the sputum may still contain eosinophils, but may also contain neutrophils or a mix of these types. The adult-onset asthma phenotype may also be associated with atopy, but many adults with asthma have a negative family history and negative skin tests to common aeroallergens. Some of these patients may have Samter triad: nasal polyps, aspirin sensitivity, and asthma. Both nonallergic and adult-onset phenotypes are less likely to be fully responsive to ICSs.[1,7] In fact, a recent trial found that many patients with persistent asthma and low sputum eosinophils failed to respond to ICSs, which is the standard controller therapy.[8]

Occupational asthma, a subset of adult-onset asthma, results from workplace exposure to various organic and inorganic substances including chemicals, wood dust, enzymes, and metals. This should be promptly investigated in adult-onset asthma because it represents a modifiable trigger that can be eliminated in these patients.[9]

Obesity-associated asthma, which is considered by some to be a separate phenotype, is, at the very least, another modifiable factor that can be present across phenotypes. Although the mechanisms underlying obesity's role in asthma are unclear, it is increasingly apparent that obesity can make it more difficult to attain adequate control of symptoms.[10]

For unknown reasons, in some patients, the failure to adequately minimize severe airway inflammation and bronchoconstriction results in structural changes characterized by increased smooth muscle and goblet cell hypertrophy and angiogenesis. These alterations in functional bronchial anatomy, termed *airway remodeling*, may lead to persistent airflow limitation, representing another phenotype.[1,7,11]

Although not a single phenotype, asthma/chronic obstructive pulmonary disease (COPD) overlap may be present in >20% of those who have been diagnosed with asthma or COPD, depending on the subset of patients studied.[12] Associated with both symptoms of asthma and COPD, this frequently includes a history of smoking or long-term exposure to biomass fuel. Because the "asthma portion" of this disease always requires an anti-inflammatory agent, correct diagnosis is vital because it is crucial to not mistakenly treat these patients as having purely COPD.

ENDOTYPES

The current paradigm of asthma inflammatory "endotypes," which is a particular cascade of interactions with certain cells and mediators that underlie the phenotypic presentation of a disease, includes T helper (Th2), high asthma. This pathway is mapped out to a greater degree and is driven by interleukin (IL)-4, IL-5, and IL-13 cytokines and eosinophilic inflammation.[1,6,7] Type 2 (T2)-low asthma is less well defined, but more often involves noneosinophilic-associated (neutrophilic or paucigranulocytic) airway inflammation and may be linked with a number of cytokines such as IL-17 produced by Th17 cells.[1,6,7] This latter endotype has proved particularly difficult to treat, with targets for therapy of T2-low disease being a focus of active research. Moreover, it is apparent that some patients have an overlap of both endotypes.[6,7,13]

BIOMARKERS

Used as a method to phenotype and guide the treatment of severe asthma, there are currently a small number of biomarkers in routine clinical use, but more are being elucidated in the research arena. Blood (which is easier to attain) and sputum eosinophils can be helpful in both monitoring and guiding the treatment of severe asthma.[14] When IgE is bound to mast cells and basophils, the binding of an allergen to these cross-linked IgE receptors results in degranulation of these cells, resulting in the release of inflammatory mediators (see Fig. 18-1). The sensitization to this allergen–IgE

complex is strongly linked to asthma, and can be both quantified as skin testing in initial evaluation of inhalant allergens in asthma and measured as serum IgE, used to guide anti-IgE treatment. One biomarker of airway inflammation, nitric oxide, can be measured by determining the fractional concentration of exhaled nitric oxide or FeNO level.[14] Although not essential in the diagnosis of asthma, FeNO has been used as a treatment guide in asthma refractory to treatment on high-dose ICSs, has been found to be elevated during periods of exacerbations, and is measurably decreased with administration of ICSs but not β_2-agonists.[1,14–16] The ERS/ATS guidelines suggest that when combined with blood eosinophils, FeNO >19.4 ppb may help in choosing which patients with severe asthma are most likely to benefit from anti-IgE therapy,[15] whereas the NIH states that although FeNO use is not required, it may be utilized as part of a comprehensive set of diagnostic and monitoring parameters.[16] The utility of periostin, an extracellular protein associated with IL-13, is currently being evaluated as another biomarker of T2 inflammation.[17]

Pathophysiology

Recent literature has focused on the “hygiene hypothesis,” an imbalance of Th2 and Th1 type T lymphocytes, to explain the marked increase in Westernized countries. Although genetics can undoubtedly play a role in the development of some patients with asthma,[18–20] researchers have also identified that the microbiology of the environment of young children can determine the likelihood of the occurrence of asthma, providing some evidence that is supportive of this epigenetic hygiene hypothesis.[21] Whether purposeful modifications of the microbiota can be designed to lessen the chance of asthma developing in a given household is undetermined as of yet.

Asthma is caused by a complex interaction between inflammatory cells and mediators. As noted in the definition of asthma, mast cells, eosinophils, T lymphocytes, neutrophils, and epithelial cells are of

central importance. The bronchial epithelium in patients with asthma has been described as fragile, with various abnormalities including destruction of ciliated cells and overexpression of epidermal growth factors.[1,2] Figure 18-1 depicts the complex interaction of cells and mediators associated with airway inflammation.

After exposure to an asthma-precipitating factor (eg, aeroallergen), inflammatory mediators are released from bronchial mast cells, macrophages, T lymphocytes, and epithelial cells. These mediators direct the migration and activation of other inflammatory cells, most notably eosinophils, to the airways.[1,6,13] Eosinophils release biochemicals (eg, major basic protein and eosinophil cationic protein) that cause airway injury, including epithelial damage, mucous hypersecretion, and increased reactivity of smooth muscle.[1,2]

T2-high mediators include Th2 lymphocytes that release the cytokines IL-4, IL-5, and IL-13, which at least partially control the activation and enhanced survival of eosinophils.[1,13] The complexity of airway inflammation is indicated by the fact that >100 inflammatory and cell signaling mediators of varying types are being investigated for a role in the pathophysiology of asthma.[6] In addition, at least 18 chemokines (eg, eotaxins) that are important in the delivery of eosinophils to the airways have been identified. Studies have shown the efficacy of monoclonal antibodies against IL4, IL5, and IL13.[22] See Case 18-8 later in this chapter regarding biologics. Other potential targets for treatment of severe asthma continue to be discovered.[13,19]

Hyperreactivity (defined as an exaggerated response of bronchial smooth muscles to trigger stimuli) of the airways to physical, chemical, immunologic, and pharmacologic stimuli is pathognomonic of asthma.[2] Examples of these stimuli include inhaled allergens; respiratory viral infection; cold, dry air; smoke; other pollutants; and methacholine. Endogenous stimuli that can worsen asthma include poorly controlled rhinitis, sinusitis, and gastroesophageal reflux disease.[2] In addition, premenstrual asthma has been reported, but the exact hormonal mechanism is not known.[23] Although patients with allergic rhinitis, chronic bronchitis, and cystic fibrosis also

experience bronchial hyperreactivity, these patients do not experience bronchiolar constriction as severely as do patients with asthma. The degree of bronchial hyperreactivity correlates with the clinical course of disease, which is characterized by periods of remissions and exacerbations. During times of remission, a more intense stimulus is required to produce bronchospasm than it is during times of increased symptoms. Numerous theories have been proposed to explain the bronchial hyperreactivity found in asthma, yet none fully explains the phenomenon. Inflammation appears to be the primary process in the pathogenesis of bronchial hyperreactivity; however, neurogenic imbalances in the airways also may play a significant role.[6,7] Hyperreactivity can be measured in the physician's office by having the patient inhale small escalating concentrations of nebulized methacholine or histamine or by exercise (eg, treadmill). The concentration of aerosolized methacholine or histamine that decreases the forced expiratory volume in 1 second (FEV_1) by 20% is referred to as the *PD20* or the *PC20* (provocative dose or provocative concentration that decreases the FEV_1 by 20%).[2] An indicator of optimal anti-inflammatory therapy is an increase in the PD20 with time because the airways become less inflamed and therefore less hyperreactive. Biphasic inflammation, "late phase" versus "early phase," is another concept related to asthma (**Fig. 18-2**). The inhalation of specific allergens in patients with atopic asthma produces immediate bronchoconstriction (measured by a drop in peak expiratory flow [PEF] or FEV_1) that spontaneously improves in an hour or is reversed easily by inhalation of a β_2-agonist. Although this early asthmatic response (EAR) is blocked by the preadministration of β_2-agonists or theophylline, a second response often occurs ~4 to 8 hours later. This late asthmatic response (LAR) often is more severe, more prolonged, and more difficult to reverse with bronchodilators than is the EAR. The LAR is associated with the influx of inflammatory cells and mediators, as described previously. Bronchodilators do not block the LAR to allergen challenge; corticosteroids block the LAR, but do not affect the EAR.[2] Pathologic changes found at autopsy performed on patients with asthma include

(a) marked hypertrophy and hyperplasia of the bronchial smooth muscle, (b) mucous gland hypertrophy and excessive mucus secretion, and (c) denuded epithelium and mucosal edema owing to an exudative inflammatory reaction and inflammatory cell infiltration.[24] Hyperinflation of the lungs from air trapping with extensive mucous plugging is found at autopsy in patients who have died of acute asthma attacks,[24] but these changes also are seen at autopsy in patients with asthma dying of other causes. The bronchial smooth muscle hypertrophy and mucous hypersecretion are secondary to the chronic inflammatory response.[2,15]

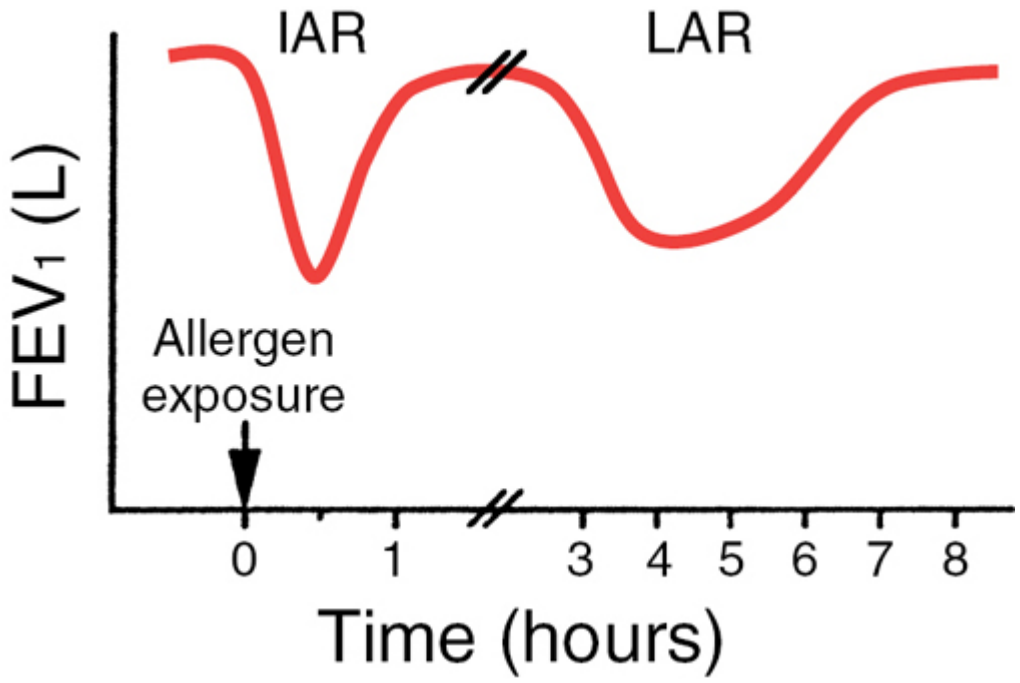

Figure 18-2 Typical immediate and late asthmatic responses seen after exposure to relevant allergen. Immediate asthmatic response (IAR) occurs within minutes, whereas late asthmatic response (LAR) occurs several hours after exposure. Patients may demonstrate isolated IAR, isolated LAR, or dual responses. FEV_1, forced expiratory volume in 1 second. Symptoms

The heterogeneity of asthma is reflected best in its clinical presentation. Classically, patients with asthma present with intermittent episodes of expiratory wheezing, coughing, and dyspnea. Some patients, however, experience chest tightness or a chronic cough that is not associated with wheezing. There is a wide spectrum of disease severity, ranging from patients with occasional, mild bouts of breathlessness to patients who wheeze daily despite continuous high dosages of medication. In addition, the severity of asthma may be influenced by environmental factors (eg, specific seasonal allergens). Symptoms often are associated with exercise and sleep (refer to Cases 18-9).

Classification of asthma severity is of major importance in defining initial long-term treatment. Within three age groups, GINA 2020 uses the classifications of mild, moderate, and severe asthma, which are determined after a patient has been on controller treatment for several months.[1] These steps represent the level of medication required to control symptoms and minimize exacerbations. This categorization is not static and may change multiple times over months or years (**Figs. 18-3**–**18-7**). Mild asthma is defined as asthma that is well controlled with step 1 or 2 treatment. Moderate asthma is defined as asthma that is well controlled on step 3 treatment. Severe asthma is defined as asthma that requires step 4 or 5 treatment.[1] Another key concept that is of extreme significance, particularly in patients with severe asthma, is differentiating between controlled and uncontrolled asthma. There may be a large disconnect between patient perception of symptoms and the clinician's viewpoint on asthma control. A study of 8000 European patients revealed that >80% of subjects who had experienced major life disruptions owing to uncontrolled asthma (ED visits, hospitalizations, or a course of oral steroids) over the previous 12 months considered that their asthma was "controlled."[25]

Diagnosis and Monitoring

HISTORY

The diagnosis of asthma is based primarily on a detailed history of intermittent symptoms of wheezing, chest tightness, shortness of breath, and coughing. These episodes may be worse seasonally (eg, springtime or late summer and early fall) or in association with exercise. History of nocturnal symptoms with awakening in the early morning is a critical component to assess. In addition, history of symptoms after exposure to other common triggers (eg, cats, bleach,

perfume, secondhand tobacco smoke) is typical (**Table 18-1**).[1,2] A positive family history and the presence of rhinitis or atopic dermatitis also are significant. After a careful history is obtained, skin testing may be useful in identifying triggering allergens, but it is only of supportive value in the diagnosis of asthma. A common adage, "all that wheezes is not asthma" is true, of which a prime example is the confusing term "cardiac asthma," which is not asthma at all, but is used to denote wheezing caused by cardiogenic pulmonary edema. A significant minority, up to one-third of patients in one series, may have been misdiagnosed with asthma, and instead were found to have alternate explanations for their symptoms.[26]

Table 18-1
Sample Questions for the Diagnosis and Initial Assessment of Asthma

A "yes" answer to any question suggests that an asthma diagnosis is likely.[a]
In the past 12 months:
Have you had a sudden severe episode or recurrent episodes of coughing, wheezing (high-pitched whistling sounds when breathing out), chest tightness, or shortness of breath? Have you had colds that "go to the chest" or take >10 days to get over? Have you had coughing, wheezing, or shortness of breath during a particular season or time of the year? Have you had coughing, wheezing, or shortness of breath in certain places or when exposed to certain things (eg, animals, tobacco smoke, perfumes)? Have you used any medications that help you breathe better? How often? Are your symptoms relieved when the medications are used?
In the past 4 weeks, have you had coughing, wheezing, or shortness of breath?
At night that has awakened you? On awakening? After running, moderate exercise, or other physical activity?

[a] These questions are examples and do not represent a standardized assessment or diagnostic instrument. The validity and reliability of these questions has not been assessed.

PULMONARY FUNCTION TESTS

The diagnosis of asthma is based in part on demonstration of reversible airway obstruction. A brief discussion of tests to detect reversibility of airway obstruction is important. Furthermore, a short summary of arterial blood gases (ABGs) is pertinent here in assessing the severity of asthma exacerbations.

Spirometry

Lung volumes often are measured to obtain information about the size of the patient's lungs because pulmonary diseases can affect the volume of air that can be inhaled and exhaled. The tidal volume is the volume of air inspired or expired during normal breathing. The volume of air blown off after maximal inspiration to full expiration is defined as the vital capacity (VC). The residual volume (RV) is the volume of air left in the lung after maximal expiration. The volume of air left after a normal expiration is the functional residual capacity (FRC). Total lung capacity (TLC) is the VC plus the RV. Patients with obstructive lung disease have difficulty with expiration; therefore, they tend to have a decreased VC, an increased RV, and a normal TLC. Classic restrictive lung diseases (eg, sarcoidosis, idiopathic pulmonary fibrosis) present with decrements in all lung volumes.[27,28] Patients also may have mixed lesion diseases, in which case the classic findings are not apparent until the disease has advanced considerably. The spirometer also can be used to evaluate the performance of the patient's lungs, thorax, and respiratory muscles in moving air into and out of the lungs. Forced expiratory maneuvers amplify the ventilation abnormalities produced. The single most useful test for ventilatory dysfunction is the FEV. The FEV is measured by having the patient exhale into the spirometer as forcefully and completely as possible after maximal inspiration. The resulting volume curve is plotted against time (**Fig. 18-8**) so that expiratory flow can be estimated.

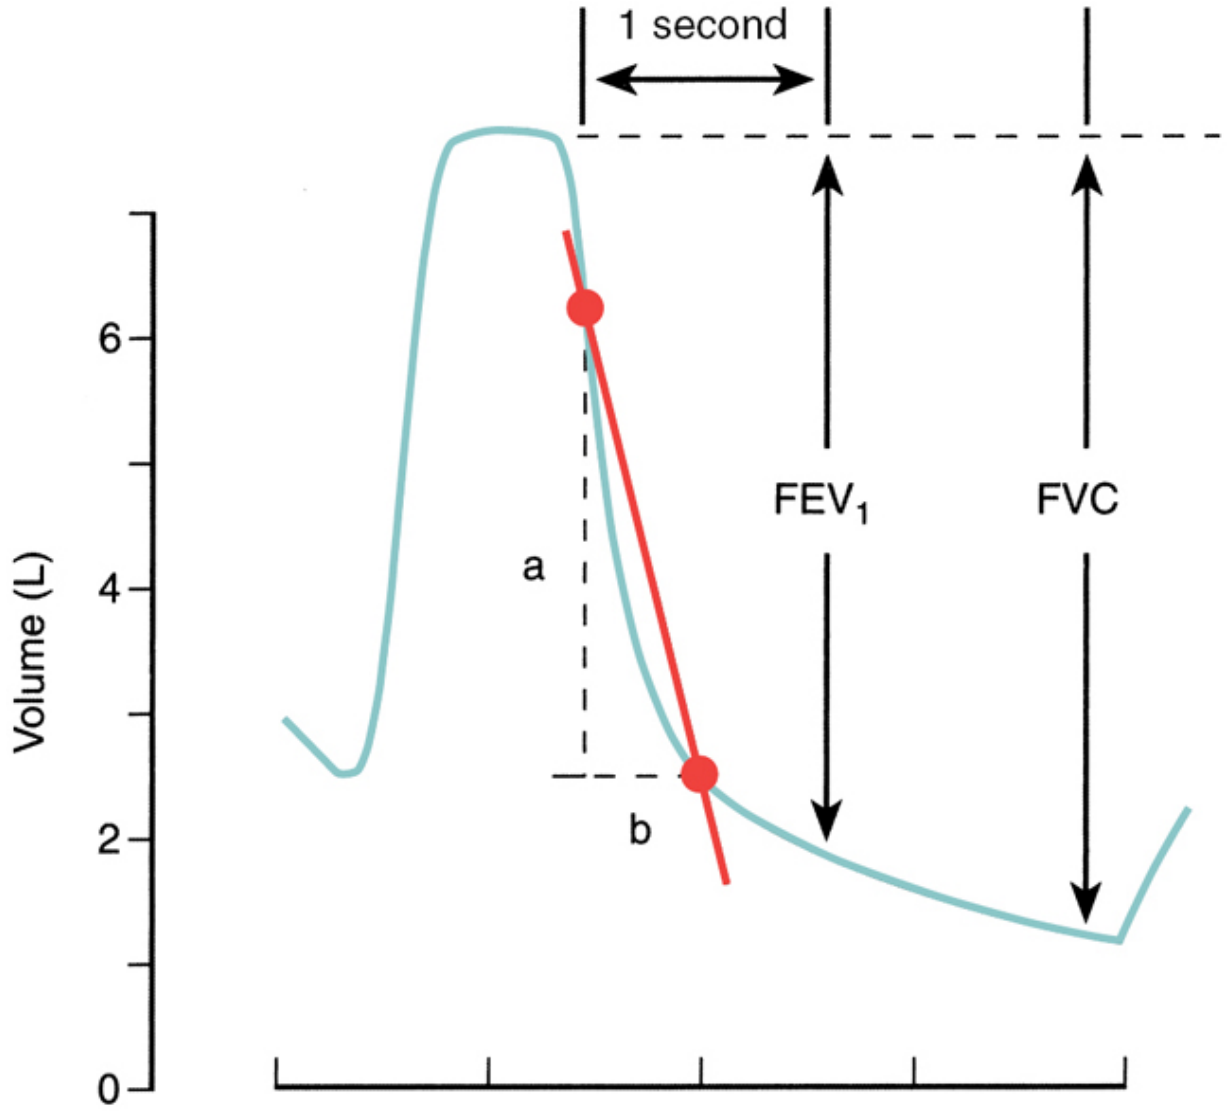

Figure 18-8 Volume–time curve from a forced expiratory maneuver. FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity.

Standard spirometers contain pneumotachographs in the mouthpieces that can measure airflow directly. A number of important measures of lung function are made from the resulting flow–volume curves. The advantages of this technique include a display of simultaneous flows at any lung volume, visual estimation of patient effort and cooperation, high reproducibility within as well as across individuals, and an analysis of the distribution of flow limitation.[28] The FEV_1 of the forced vital capacity (FVC, the maximal

volume of air exhaled with maximally forced effort from a position of maximal inspiration) commonly is measured to determine the dynamic performance of the lung in moving air. The FEV_1 usually is expressed as a percentage of the total volume of air exhaled and is reported as the FEV_1-to-FVC ratio.[27] Healthy persons generally can exhale at least 75% to 80% of their VC in 1 second and almost all of it in 3 seconds. Thus, the FEV_1 normally is 80% of the FVC. The patient's breathing ability is compared against "predicted normal" values for patients with similar physiologic characteristics because lung volumes depend on age, race, sex, height, and weight. For example, an average-sized young adult male may have an FVC of 4 to 5 L, and a corresponding FEV_1 of 3.2 to 4 L. The FEV_1 and the FVC are the most reproducible of the pulmonary function tests.

For a video that shows how to take a lung function test, see

https://www.nationaljewish.org/conditions/tests-procedures/pulmonary-physiology/pulmonary-function/spirometry.

Peak expiratory flow

The PEF is the maximal flow that can be produced during forced expiration. The PEF can be measured easily with various handheld peak flow meters and commonly is used in EDs and clinics to quickly and objectively assess the effectiveness of bronchodilators in the treatment of acute asthma attacks. The changes in PEF generally parallel those of the FEV_1; however, the PEF is a less reproducible measure than the FEV_1.[1] A healthy, average-sized middle-aged adult female typically has a PEF of 400 to 500 L/minute. Peak flow meters come with a chart for patients to determine their predicted normal PEFs based on their sex, age, and height. These devices are affordable for most, available without a prescription, and can be an essential part of home monitoring, particularly to those patients who

are not as sensitive to changes in lung function or who have a history of exacerbations requiring oral corticosteroids (OCSs). It is important to use the same device when documenting PEF because there is some variation between brands.

For a video that shows how to take a lung function test,

https://www.lung.org/lung-health-diseases/lung-disease-lookup/asthma/living-with-asthma/managing-asthma/measuring-your-peak-flow-rate.

OBSTRUCTIVE VERSUS RESTRICTIVE AIRWAY DISEASE

Generally, pulmonary disorders fall into two categories: those that restrict the lungs and thorax and those that obstruct them. In simplest terms, restrictive disease limits airflow during inspiration, and obstructive disease limits airflow during expiration. Restrictive disease results from a loss of elasticity (eg, fibrosis, pneumonia) or physical deformities of the chest (eg, kyphoscoliosis), with a consequent inability to expand the lung and a reduced TLC, although the FEV_1/FVC ratio may still be >70%. Restrictive airway diseases limit lung expansion, whereas obstructive airway diseases (eg, bronchitis, asthma) narrow air passages, create air turbulence, and increase resistance to airflow. In obstructive diseases, maximal expiration may begin at higher than normal lung volumes, and the expiratory flow is depressed.

REVERSIBLE AIRWAY OBSTRUCTION

Spirometry often is used to determine the reversibility of airway disease. Although many generally associate reversibility with bronchospasm, therapy can improve airflow by reversing any of the causative pathologic processes of asthma described previously. Significant clinical reversibility produced from bronchodilators is determined by the tests outlined in **Figure 18-9**. The FEV_1 is considered the gold standard test for determining reversibility of

airway disease and bronchodilator efficacy. Significant clinical reversibility is defined as a >200 mL and >12% improvement in FEV_1 after administration of a short-acting bronchodilator.[1] An improvement of 20% in FEV_1 provides noticeable subjective relief of respiratory symptoms in most patients. For patients with a very low baseline FEV_1 (eg, <1 L), an absolute improvement of 250 mL sometimes is considered a better indicator of therapeutic benefit than is assessing the percentage of change. In either case, the patient's subjective clinical impression also should be considered when using pulmonary function testing and drug challenges as predictors for future therapy.

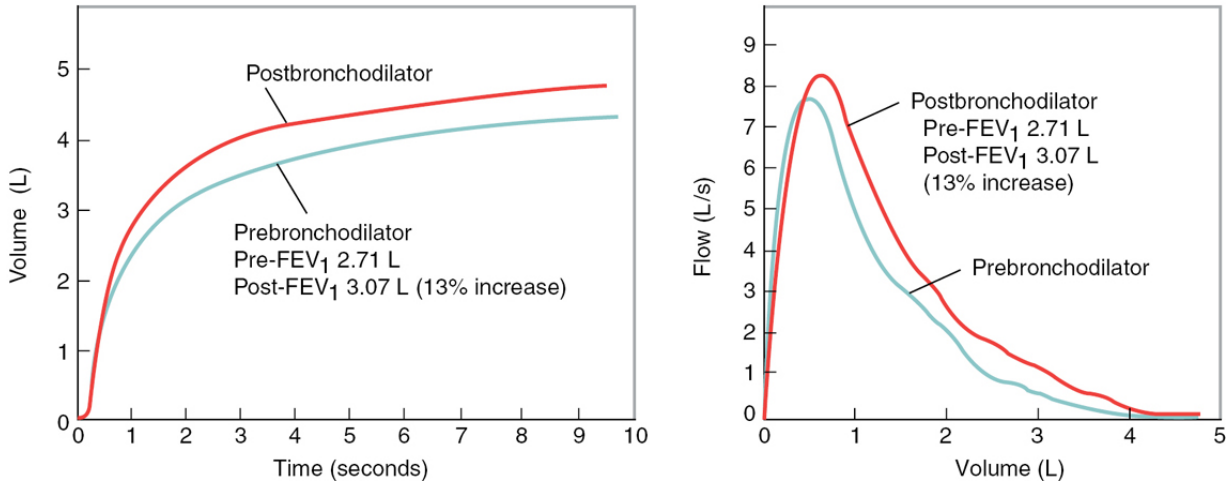

Figure 18-9 Interpretation of results of spirometry. The graphs depicted are for illustration only. The interpretation of flow rates may vary with the age of the patient. FEV_1, forced expiratory volume in 1 second. (Adapted from National Institutes of Health. *Expert Panel Report 2. Guidelines for the Diagnosis and Management of Asthma*. National Heart, Lung, and Blood Institute; 1997. NIH publication no. 97-4051.)

BLOOD GAS MEASUREMENTS

The best indicators of overall lung function (ventilation and diffusion) are the ABGs (ie, arterial partial pressure of oxygen [Pao_2], arterial partial pressure of carbon dioxide [$Paco_2$], and pH). Although ABG

measurements also are dependent on the patient's cardiovascular status, they are indispensable in assessing both acute and chronic changes in pulmonary patients (see Chapter 26, Acid–Base Disturbances, for a review of ABGs). However, obtaining ABGs is more painful for the patient than is a venous blood draw and is only required in the more severe cases. Another means of assessing the patient's ability to oxygenate tissues adequately is to measure oxygen saturation, which is described by the following equation:

$$\text{O}_2\text{ saturation} = \text{Quantity of O}_2\text{ actually bound to hemoglobin} / \text{Quantity of O}_2\text{ that can be bound to hemoglobin} \times 100. \quad \textbf{(Eq. 18-1)}$$

According to this equation, oxygen saturation is the ratio between the actual amount of oxygen bound to hemoglobin and the potential amount of oxygen that could be bound to hemoglobin at a given pressure. The denominator in the preceding equation is the oxygen capacity. The normal oxygen saturation of arterial blood at a Pao_2 of 100 mm Hg is 97.5% and that of mixed venous blood ($ScVO_2$) at a Po_2 of 40 mm Hg is about 75%.

Oxygen saturations can be measured continuously with transcutaneous monitors. This type of monitoring (pulse oximetry) is extremely helpful in determining whether supplemental oxygen therapy is indicated in patients with various chronic respiratory diseases. At a Pao_2 of <60 mm Hg, oxygen saturation begins to drop precipitously (**Fig. 18-10**). Although a significant elevation in pCO_2 (hypercapnia) may occur in severe asthma exacerbations, portending a need for intubation, a variety of acid–base and blood gas abnormalities may be seen in various stages of an asthma attack.

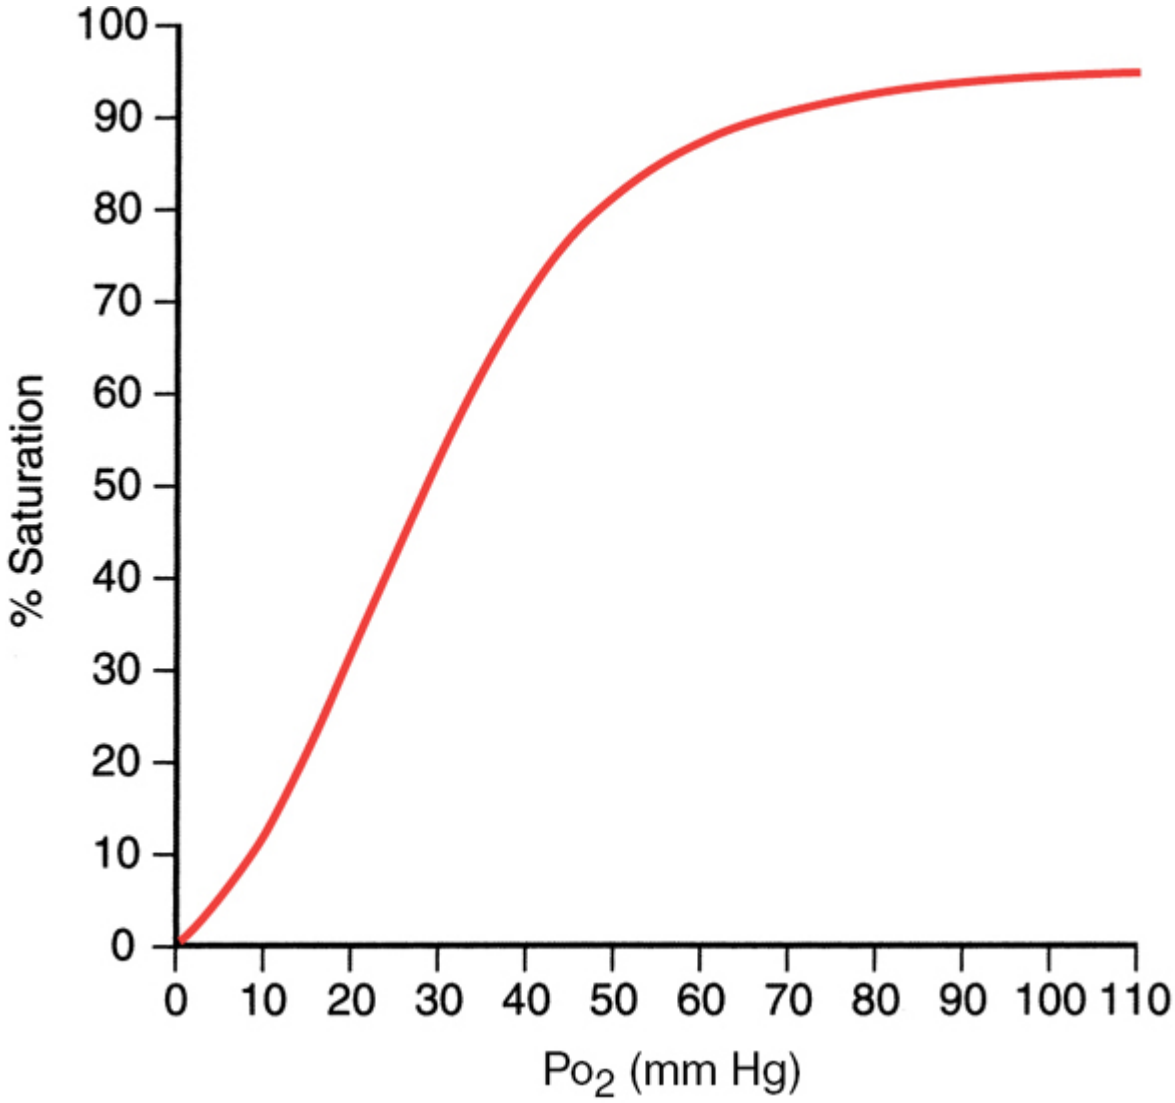

Figure 18-10 The oxygen dissociation curve reveals that the percent saturation of hemoglobin increases almost linearly with increases in the arterial O_2 tension until a partial pressure of arterial oxygen (Pao_2) of 55 to 65 mm Hg is reached. At Pao_2 values above this, the increase in hemoglobin saturation becomes proportionately less, and relatively little additional oxygen is added to the hemoglobin despite large increases in Pao_2. Goals of Therapy

Reduce impairment: (a) Prevent chronic and troublesome symptoms (eg, coughing or breathlessness in the night, in the early morning, or after exertion); (b) maintain (near) "normal" pulmonary function; (c) maintain normal activity levels (including exercise, other physical activities, and attendance at work or school); and (d) meet patients' and families' expectations of and satisfaction with asthma care.[1,2]

Reduce risk: (a) Prevent recurrent exacerbations of asthma and minimize the need for ED visits or hospitalizations; (b) prevent progressive loss of lung function—for children, prevent reduced lung growth; and (c) provide optimal pharmacotherapy with minimal or no adverse effects.

CASE 18-1

QUESTION 1: Q.C., a 6-year-old 44.09-pound (20-kg) girl, presents to the ED with dyspnea and coughing that have progressively worsened during the past 2 days. These symptoms were preceded by 3 days of an upper viral respiratory infection. She has experienced several bouts of acute bronchitis in the past 2 years and was hospitalized with pneumonia 3 months ago. She is not being treated with any medications as an outpatient. Physical exam reveals an anxious-appearing young girl in moderate respiratory distress with audible wheezing, coughing, a prolonged expiratory phase, a hyperinflated chest, and obvious use of sternocleidomastoid and trapezius muscles to help her breathe. Bilateral inspiratory and expiratory wheezes are heard on auscultation. Vital signs: respiratory rate (RR) 30, blood pressure (BP) 110/83, pulse 130 beats/minute, and pulsus paradoxus measured at 18 mm Hg. Her O_2 saturation is 89%, so she is started on 1 L of oxygen by face mask, which is titrated up to maintain a saturation of 94% to 98%. Albuterol, 2.5 mg per nebulizer is administered every 20 minutes in three doses, plus budesonide 1000 µg per nebulizer in one dose. She initially feels better, but then begins to wheeze louder.

What signs and symptoms in Q.C. are consistent with acute bronchial obstruction? Does increased wheezing after albuterol indicate failure of treatment?

Asthma is an obstructive lung disease; therefore, the primary limitation to airflow occurs during expiration. This outflow obstruction leads to the classic findings of dyspnea, expiratory wheezes, and a prolonged expiratory phase during the ventilatory cycle.[1] Wheezing

is a whistling sound produced by turbulent airflow through a constricted opening and is usually more prominent on expiration as opposed to stridor, which is a pronounced high-pitched sound made on inspiration and is associated with significant large airway obstruction, as seen in viral croup or epiglottitis. Thus, the audible expiratory wheezing in Q.C. is compatible with bronchial obstruction. In fact, Q.C.'s obstruction is so severe that even inspiratory wheezes and decreased air movement were detected on auscultation. It is important to realize that the classic symptom of wheezing requires turbulent airflow; therefore, effective therapy of acute asthma may actually result in increased wheezing initially because airflow increases throughout the lung. As a result, Q.C.'s increased wheezing on auscultation is compatible with her clinical improvement after the albuterol nebulizer treatments. The coughing experienced by Q.C. is another common finding associated with acute asthma attacks. The coughing may be caused by stimulation of "irritant receptors" in the bronchi by the chemical mediators of inflammation (eg, leukotrienes) that are released from mast cells or from the mechanics of smooth muscle contraction. In the progression of an asthma attack, the small airways become completely occluded during expiration, and air can be trapped behind the occlusion; therefore, the patient must breathe at higher than normal lung volumes.[2] Consequently, the thoracic cavity becomes hyperexpanded, and the diaphragm is lowered. As a result, the patient must use the accessory muscles of respiration to expand the chest wall. Q.C.'s hyperinflated chest and her use of accessory muscles to assist in breathing also are compatible with obstructive airway diseases.

Occlusion of the small airways, air trapping, and resorption of air distal to the obstruction can lead to atelectasis (incomplete expansion or collapse of pulmonary alveoli or of a segment of a lobe of the lung). Localized areas of atelectasis often are difficult to distinguish from infiltrates on a chest radiograph, and atelectasis can be mistaken for pneumonia. Q.C.'s history of multiple bouts of "bronchitis" is significant and typical of many young patients with asthma. In any patient with recurring episodes of bronchial

symptoms (eg, bronchitis, pneumonia), the possible diagnosis of asthma should be investigated.

The increased pulse, RR, and anxiety experienced by Q.C. can be attributed to both the hypoxemia and the feeling of suffocation. The hypoxemia in acute asthma is caused principally by an imbalance between alveolar ventilation and pulmonary capillary blood flow, also known as ventilation–perfusion ($\dot{V}/\dot{Q}$) mismatching. Each alveolus of the lung is supplied with capillaries from the pulmonary artery for gas exchange. When ventilation is decreased to an area of the lung, the alveoli in that area become hypoxic, and the pulmonary artery to that region constricts as a normal physiologic response. As a result, blood flow is shunted to the well-ventilated portions of the lung because of the need to preserve adequate oxygenation of the blood. The pulmonary arteries, however, are not constricted completely, and when a small amount of blood flows to the poorly ventilated alveoli, mismatching is the result. Conditions of diffuse bronchial obstruction (ie, acute asthma) increase the amount of mismatching. In addition, some mediators of acute bronchospasm (eg, histamine) further worsen mismatching by constricting bronchial smooth muscle while concurrently relaxing vascular smooth muscle. Q.C. also demonstrated a significant pulsus paradoxus. Pulsus paradoxus is defined as a drop in systolic BP of >10 mm Hg with inspiration. In general, pulsus paradoxus correlates with the severity of bronchial obstruction; however, it is not always present.[2]

EXTENT OF OBSTRUCTION

Case 18-1, Question 2: What additional tests would be helpful in assessing the extent of pulmonary obstruction in Q.C.?

Chest radiographs are routinely helpful in assessment of asthma but should be obtained in patients who are suspected of having a complication (eg, pneumonia).[1] Hyperinflated lungs and areas of atelectasis can be seen on a chest x-ray film; however, chest x-ray studies usually are negative and of little value in evaluating acute

asthma attacks. The finding of a local decrease in breath sounds in Q.C.'s left lung may justify the need for a chest x-ray study, particularly if a significant differential in air movement persists after initial therapy. A local decrease in breath sounds may indicate pneumonia, aspiration of a foreign object, pneumothorax, or merely thickened mucous plugging of a large bronchus.

Pulmonary function testing (eg, FEV_1, PEF) provides objective measurement of the degree of airway obstruction. Peak flow meters are helpful in the ED for assessing both the severity of airway obstruction and the response to bronchodilator therapy. Unfortunately, infants and many young children do not have the cognitive or motor skills necessary to perform pulmonary function tests. In one study, only 65% of children ages 5 to 16 years could complete either FEV_1 or PEF during an acute exacerbation. Because of Q.C.'s initial anxiety, the PEF should be measured after bronchodilator therapy has been initiated, when she may be calmer. One disadvantage of pulmonary function tests in acute asthma is that the forced expiratory maneuver commonly triggers coughing. ABG measurements are the gold standard for assessing very severe airway obstruction.[1,2] GINA suggests ABGs for evaluation of patients who have not responded to initial treatment, are in severe distress, or in whom the FEV_1 or PEF is <50%.

ABG measurements are indicated in patients who fail to respond adequately to initial therapy or in patients requiring hospitalization; they are not indicated at this time for Q.C. A repeat pulse oximetry at 1 hour after treatment initiation is warranted in Q.C. to ensure adequate arterial oxygen saturation.

NEED FOR HOSPITALIZATION

CASE 18-1, QUESTION 3: Q.C. may require hospitalization. Which clinical test is predictive of the need for admission or whether Q.C. will relapse if sent home from the ED? Are Q.C.'s signs and symptoms predictive of whether she will relapse and return to the ED if not hospitalized?

Although Q.C. is not able to perform spirometry, she is able to execute the PEF maneuver, and the plan is to check her PEF after 1 hour of therapy. Signs and symptom scores alone are not adequate to predict the outcome of ED treatment of asthma, but scores along with pulse oximetry and PEF or FEV_1 are helpful predictors.[2] There have been several predictive scores and pathways to determine the probability of hospital admission that do not rely on PEF of FEV_1 because these may be difficult to obtain, especially in pediatric patients. A decrease in O_2 saturations from 98% to 94% and an inspiratory-to-expiratory ratio of ≤1 to 3 were found to be the two strongest components of the Asthma Prediction Rule associated with the need for hospitalization.[29] Assessment of the response to treatment at regular intervals is essential. Primary care and emergency care management of children ages 5 years and younger with asthma exacerbations is listed in GINA.[1]

CASE 18-1, QUESTION 4: Why was albuterol selected as the bronchodilator of choice in preference to other bronchodilators such as levalbuterol, ipratropium, or subcutaneous (SC) terbutaline? Why did Q.C. receive inhaled budesonide?

Because of their potency and rapidity of action, short-acting β_2-agonists (SABAs) are considered the first choice for the treatment of acute asthma.[1,2] The bronchodilatory properties of SABAs are particularly effective in reversing early-phase asthma responses.[1,2] Although levalbuterol is effective, its increased cost and minimally different side effect profile as compared to albuterol make it unpractical for regular use.[30] Similarly, the bronchodilation from the anticholinergic drug ipratropium is of smaller magnitude than it is with inhaled SABAs.[2] Although SC terbutaline is effective in severe asthma, current guidelines discourage routine use of parenteral β_2-agonists, and most clinicians reserve their use in rare situations where nebulized albuterol is ineffective or unable to be administered. Early addition of inhaled ipratropium in adequate doses to SABAs has produced mixed results but may improve pulmonary function

tests in some patient populations.[31,32] Q.C.'s physician chose to use only inhaled SABAs initially because Q.C. was not severely ill.

Although ICSs are properly positioned as controller medication for asthma, there is evidence that administration of ICSs in acute asthma in addition to systemic steroids can decrease hospital admissions.[33,34] The prescriber decided that even if this dose of budesonide did not help her significantly, there was no harm. If she does not get admitted to this hospital, prescribing ICSs from the ED on discharge can expedite the patient getting started on appropriate therapy than waiting for the outpatient clinician to do so.[2]

Case 18-1, Question 5: Q.C. received albuterol by nebulization. Would metered-dose aerosol administration of the albuterol have been inferior? What is a comparable dose of albuterol given by metered-dose inhaler (MDI) versus via nebulizer?

Aerosols are mixtures of particles (eg, a drug–lipid mixture) suspended in a gas. An MDI consists of an aerosol canister and an actuation device (valve). The drug in the canister is a suspension or solution mixed with propellant. The valve controls the delivery of drug and allows the precise release of a premeasured amount of the product. A second aerosol device, the air jet nebulizer, mechanically produces a mist of drug. The drug is placed in a small volume of solute (typically 3 mL of saline) and then placed in a small reservoir (nebulizer) connected to an air source such as a small compressor pump, an oxygen tank, or a wall air hose. Air travels from the relatively large-diameter tubing of the air source into a pinhole-sized opening in the nebulizer. This creates a negative pressure at the site of the air entry and causes the drug solution in the bottom of the nebulizer reservoir to be drawn up through a small capillary tube, where it then encounters rapid airflow. The drug solution is forced against a small baffle that causes mechanical formation of a mist. An ultrasonic nebulizer is a type of nebulizer that uses sound waves to generate the aerosol.

Studies that compared nebulization with pressurized metered-dose aerosols in stable patients with chronic asthma have shown no

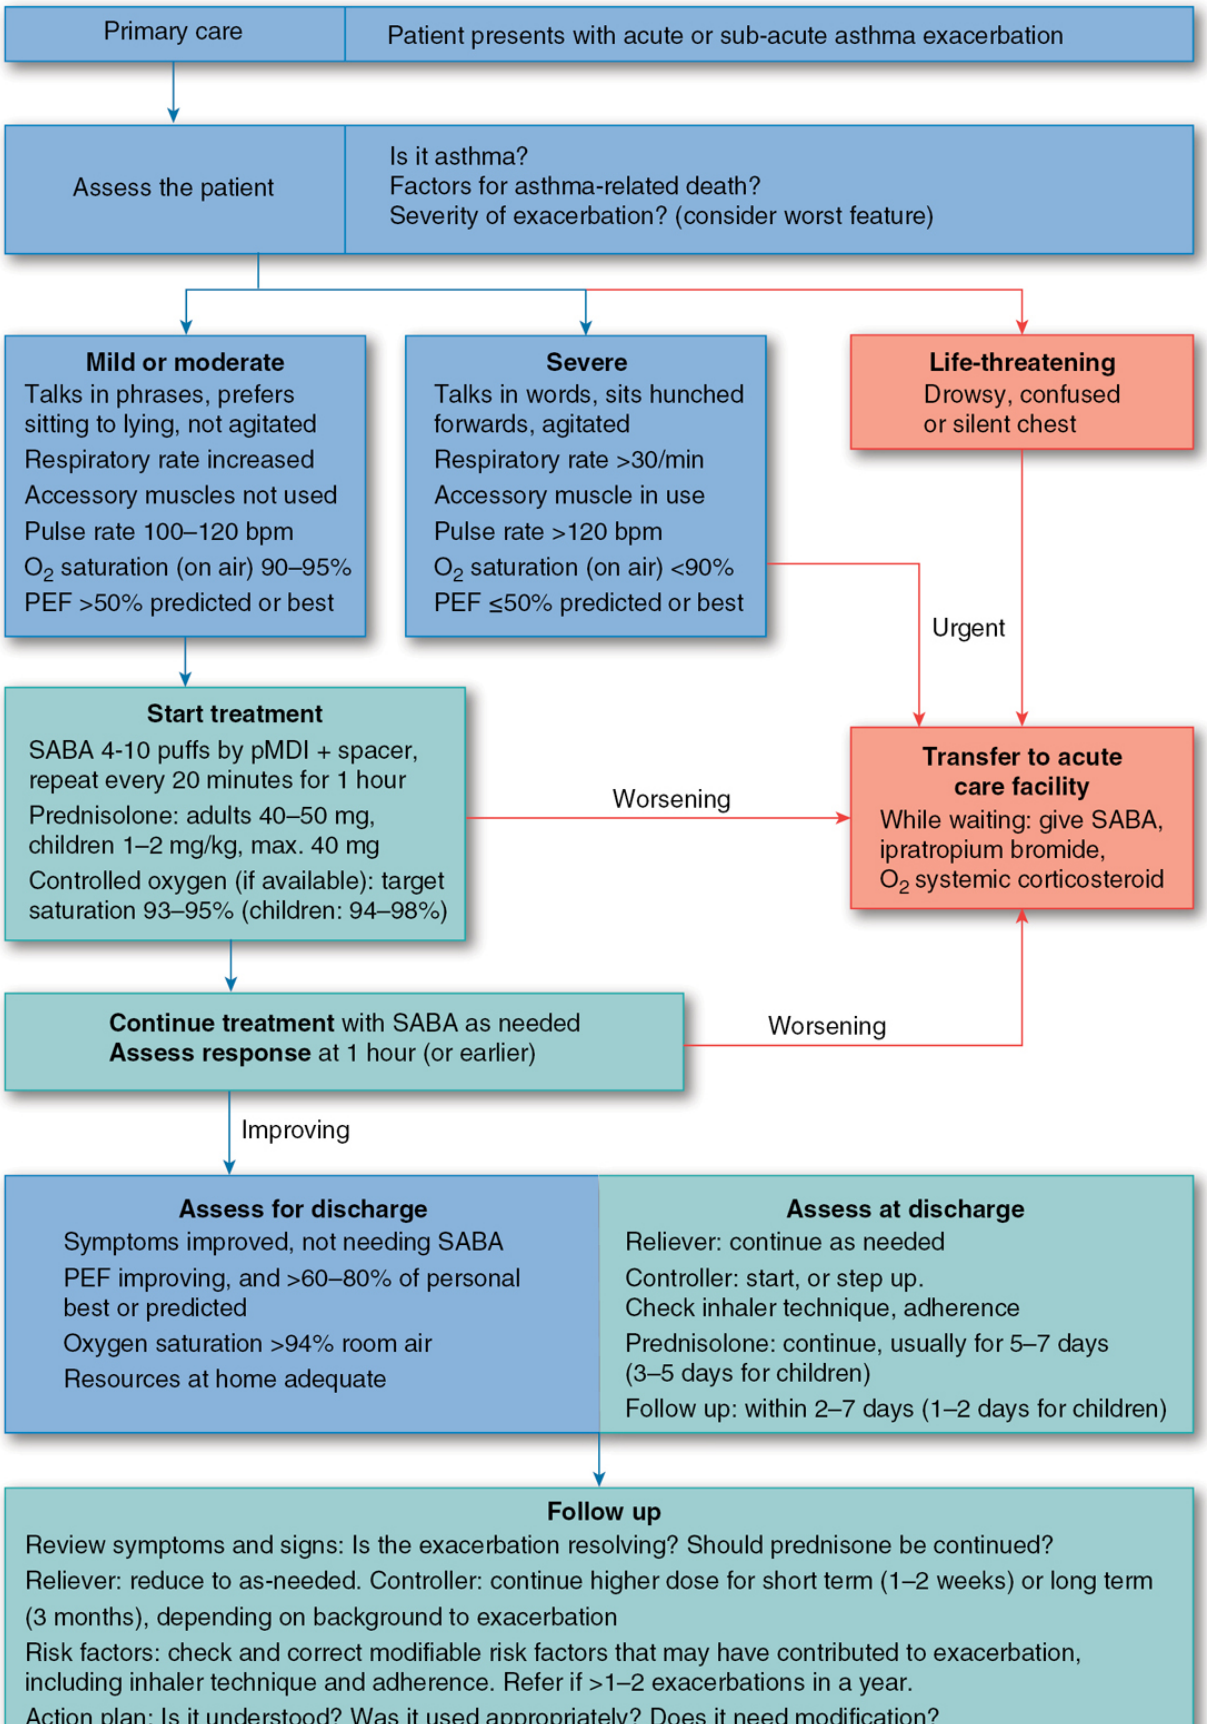
advantage among these methods of administration when equivalent doses are administered.[35] Trials comparing metered-dose aerosols of inhaled SABAs with the nebulization of those same drugs in acute asthma also have shown no significant advantage for the nebulization method of administration when the metered-dose aerosolized administration was carefully supervised by experienced personnel and a spacer device was used.[36] One pediatric randomized study from Iramain et al found that children with acute severe asthma had a significantly reduced rate of hospitalization if given ipratropium with albuterol with MDI as compared to the same drugs administered by nebulizer in the ED.[37] However, in some younger acutely ill children, it is difficult (even with supervision) to administer an effective SABA with a metered-dose canister. Because many patients and clinicians perceive that nebulizers provide more intensive therapy, it often is important psychologically to give at least the first dose of a SABA via a nebulizer. Thereafter, it is more cost effective to use the therapeutically equivalent MDI plus spacer.

An albuterol MDI contains 90 µg per actuation (puff), whereas a standard dose of albuterol given via nebulizer is 2.5 mg. Although not precise, it is generally accepted that in practical use, four to six inhalations of 90 µg per actuation of albuterol is approximately equivalent to a 2.5 mg albuterol "breathing treatment" administered via nebulizer. In a recent study of pediatric patients presenting to the ED, the investigators used four, six, or eight puffs of albuterol MDI for patients weighing <22.04 pounds (<10 kg), 22.04 to 44.09 pounds (10–20 kg), or >44.09 pounds (>20 kg) in a trial designed to increase efficiency compared to standard albuterol nebulizer treatments for mild-to-moderate asthma. The result was both a decrease in length of stay and admission rate in those patients after this albuterol MDI protocol was initiated.[38]

Case 18-1, Question 6: Starting 20 minutes after the first albuterol dose, two more doses of 2.5 mg albuterol were given via nebulizer every 20 minutes during the next 40 minutes. After three treatments, Q.C.'s breath sounds became increasingly clear. She was no longer in distress and could speak in complete sentences. Her PEF was now 70% of predicted, her O_2 saturations

were 97% on room air, with a discharge to home planned. Were the dose and interval of albuterol appropriate for Q.C.?

Schuh et al[39] were the first investigators to demonstrate that a higher dose albuterol regimen (0.15 vs 0.05 mg/kg every 20 minutes) produced significantly greater improvement with no greater incidence of adverse effects. Schuh et al[40] subsequently reported greater efficacy of albuterol in a dose of 0.3 mg/kg (up to 10 mg) hourly compared with a dose of 0.15 mg/kg (up to 5 mg) hourly in children. The larger dose was tolerated as well as the 0.15 mg/kg dose. Therefore, Q.C.'s albuterol regimen of 2.5 mg (0.13 mg/kg) nebulized 20 minutes for 40 minutes subsequent to her first dose of aerosolized albuterol could have been even more aggressive, but was appropriate. **Figures 18-11** and **18-12** provide treatment guidelines for the ED and hospital management of asthma.[1] Drug dosing recommendations are listed per GINA.[1]



Primary care
Patient presents with acute or sub-acute asthma exacerbation
Assess the patient
Is it asthma?
Factors for asthma-related death?
Severity of exacerbation? (consider worst feature)
Mild or moderate
Talks in phrases, prefers sitting to lying, not agitated
Respiratory rate increased
Accessory muscles not used
Pulse rate 100–120 bpm
O2 saturation (on air) 90–95%
PEF >50% predicted or best
Severe
Talks in words, sits hunched forwards, agitated
Respiratory rate >30/min
Accessory muscle in use
Pulse rate >120 bpm
O2 saturation (on air) <90%
PEF ≤50% predicted or best
Life-threatening
Drowsy, confused or silent chest
Urgent
Start treatment
SABA 4-10 puffs by pMDI + spacer, repeat every 20 minutes for 1 hour
Prednisolone: adults 40–50 mg, children 1–2 mg/kg, max. 40 mg
Controlled oxygen (if available): target saturation 93–95% (children: 94–98%)
Worsening
Transfer to acute care facility
While waiting: give SABA, ipratropium bromide, O2 systemic corticosteroid
Continue treatment with SABA as needed
Assess response at 1 hour (or earlier)
Worsening
Improving
Assess for discharge
Symptoms improved, not needing SABA
PEF improving, and >60–80% of personal best or predicted
Oxygen saturation >94% room air
Resources at home adequate
Assess at discharge
Reliever: continue as needed
Controller: start, or step up. Check inhaler technique, adherence
Prednisolone: continue, usually for 5–7 days (3–5 days for children)
Follow up: within 2–7 days (1–2 days for children)
Follow up
Review symptoms and signs: Is the exacerbation resolving? Should prednisone be continued?
Reliever: reduce to as-needed. Controller: continue higher dose for short term (1–2 weeks) or long term (3 months), depending on background to exacerbation
Risk factors: check and correct modifiable risk factors that may have contributed to exacerbation, including inhaler technique and adherence. Refer if >1–2 exacerbations in a year.
Action plan: Is it understood? Was it used appropriately? Does it need modification?

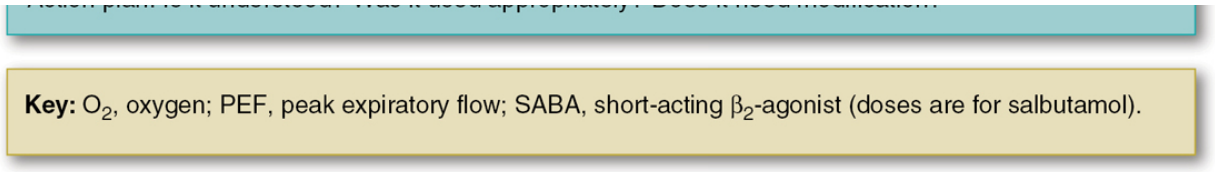


Figure 18-11 Management of asthma exacerbation in primary care (adults, adolescents, and children ages 6–11 years.)

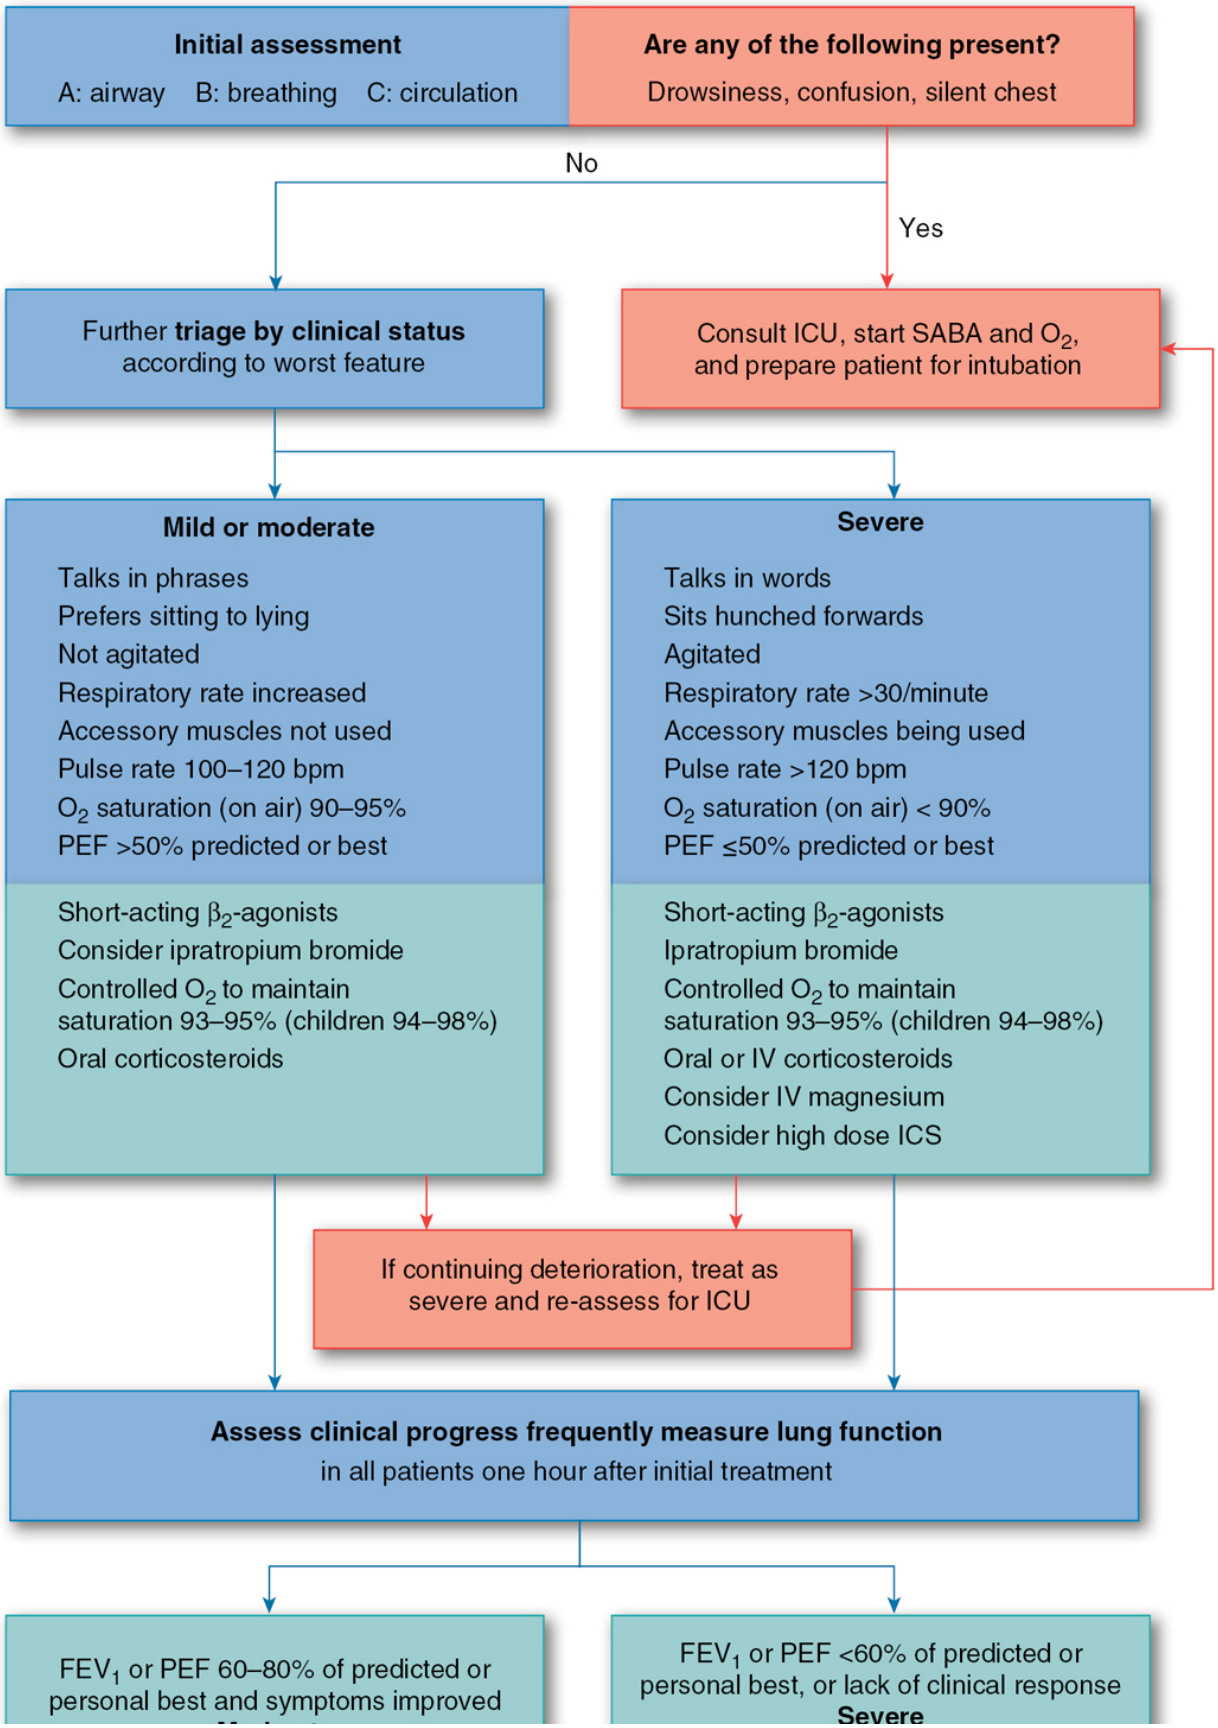

Initial assessment
A: airway B: breathing C: circulation
Are any of the following present?
Drowsiness, confusion, silent chest
No
Yes
Further triage by clinical status according to worst feature
Consult ICU, start SABA and O_2, and prepare patient for intubation
Mild or moderate
Talks in phrases
Prefers sitting to lying
Not agitated
Respiratory rate increased
Accessory muscles not used
Pulse rate 100–120 bpm
O_2 saturation (on air) 90–95%
PEF >50% predicted or best
Short-acting β_2-agonists
Consider ipratropium bromide
Controlled O_2 to maintain saturation 93–95% (children 94–98%)
Oral corticosteroids
Severe
Talks in words
Sits hunched forwards
Agitated
Respiratory rate >30/minute
Accessory muscles being used
Pulse rate >120 bpm
O_2 saturation (on air) < 90%
PEF ≤50% predicted or best
Short-acting β_2-agonists
Ipratropium bromide
Controlled O_2 to maintain saturation 93–95% (children 94–98%)
Oral or IV corticosteroids
Consider IV magnesium
Consider high dose ICS
If continuing deterioration, treat as severe and re-assess for ICU
Assess clinical progress frequently measure lung function
in all patients one hour after initial treatment
FEV_1 or PEF 60–80% of predicted or personal best and symptoms improved
FEV_1 or PEF <60% of predicted or personal best, or lack of clinical response
Severe

SYSTEMIC CORTICOSTEROIDS IN THE EMERGENCY DEPARTMENT FOR CHILDREN

CASE 18-1, QUESTION 7: Should Q.C. receive systemic corticosteroid therapy as part of her ED management?

Yes. Because asthma is primarily an inflammatory airway disease, the degree of inflammation associated with Q.C.'s current exacerbation should be considered. Per GINA,[1] if there is not an immediate response to inhaled β_2-agonist therapy, systemic corticosteroids should be administered (refer to further discussion of this subject in Case 18-3). Furthermore, if Q.C. had a peak flow meter at home, earlier objective detection of the development of this exacerbation might have prevented an ED visit. When the PEF is in the red zone (<50% of personal best) and poorly responsive to SABAs, early intervention with OCSs is associated with a reduction in ED visits[1] (see Fig. 18-9; refer to the Outcomes section at the end of the chapter). Q.C. and her parents should also understand that if respiratory distress is severe and nonresponsive to treatment, they should proceed to an ED or call 9-1-1. Finally, before going home from the ED, Q.C. and her parents should receive some basic education regarding asthma and its acute and long-term management. It is important to follow up with more detailed education during future clinic visits. According to GINA,[1] Q.C. should receive a short course of systemic corticosteroids as part of her discharge plan, thereby reducing her risk of reexacerbation.

Typically, oral prednisolone solution at a dose of 1 to 2 mg/kg/day to a maximum of 40 mg for 3 to 5 days is adequate. Prescribing ICSs on discharge from the ED may increase the chances of receiving appropriate therapy before the first follow-up visit in the office.[41]

Adverse effects

CASE 18-2

QUESTION 1: H.T. is a 45-year-old, 200.62-pound (91-kg) male with a long history of asthma, presenting to the ED with severe dyspnea and wheezing, tremors, and palpitations. He has been taking one inhalation of 220 µg mometasone twice daily, which has controlled his symptoms fairly well over the past year. However, after his cousin brought his two ferrets along to visit him for a few days, he immediately started wheezing, which fluctuated somewhat, but never resolved and gradually worsened. On the second day of using his Primatene Mist® (an MDI available over the counter [OTC] that he picked up at a chain drug store after losing his albuterol inhaler) eight times per day, he remembered being instructed to use his new budesonide160 µg/formoterol 4.5 µg as a reliever. Consequently, after 2 days of being exposed to the ferrets, he started using two puffs every 4 hours (around the clock) of this new budesonide/formoterol inhaler. The next morning on his way to the hospital, H.T. began using his Primatene Mist® plus his albuterol inhaler, which he found in his truck, since his breathing was becoming more labored, and he felt that no single one of his inhalers was working well.

Heart rate 120–160 s
RR 30/minute
Pulsus paradoxus 18 mm Hg
BP 160/100 mm Hg
ABGs on room air:
PH 7.3
Pao_2 60 mm Hg
Serum electrolyte concentrations were as follows:
Sodium 140 mEql/L
Potassium 3.1 mEql/L
Chloride 102 mEq/L
Bicarbonate 19 mEq/L

How would you critique his use of inhalers?

Albuterol has an acceptable safety profile and is generally considered the SABA of choice in most settings. Although the standard initial albuterol dose given via nebulizer is 2.5 mg, higher doses, up to 15 mg/hour can be given in acute asthma in the ED setting.[2] Skeletal muscle tremor, tachycardia, hypokalemia, and adverse effects related to its sympathomimetic activity may be observed, particularly at higher doses.[2] Formoterol is a long-acting β-agonist (LABA) that produces bronchodilation rapidly, similar to albuterol, but this agent is no longer commercially available as a standalone option in the United States. Mometasone/formoterol and budesonide/formoterol are the two products that the U.S. Food and Drug Administration (FDA) approved for the treatment of asthma in the United States.

However, per the FDA-approved labeling from the manufacturer, the maximum daily dose of formoterol is 18 μg (2 × 4.5 μg inhalations twice daily) as part of the combination product with budesonide, meaning that H.T. was taking a total of 12 inhalations (54 μg of formoterol daily). ICS/LABA as both the controller and quick relief therapy was shown to lower risk of asthma exacerbations in a recent meta-analysis of 16 trials when compared with traditional monotherapy with ICS and prn SABA.[42] Although the symbicort given as needed in mIld asthma (SYGMA) 2 trial[43] allowed adult subjects to take up to 12 inhalations of budesonide/formoterol, and the 2020 NIH guidelines[16] likewise lists 54 μg of formoterol as the maximum total daily dose in patients age older than 12 years, this is an unusually high dose and an indication that H.T. needs prompt evaluation. Overuse of these three different β-agonists was the most likely the etiology of the supraventricular tachycardia (SVT) and the hypokalemia and strongly emphasizes the need for education. However, H.T. gets his prescription inhalers from a mail order company in another state, so he never speaks with a pharmacist, and only glances at the enclosed education before he throws it and the box away (which displays the dosing directions).

Other additive causes of cardiac effects must also be considered, such as hypoxemia, which is also a potent stimulus for cardiac arrhythmias. Therefore, although H.T.’s tachycardia was most likely

caused by the inadvertent toxic dose of β_2-agonists, the worsening of his airway obstruction (as reflected in the increase in $Paco_2$), could have also contributed.

The decrease in the serum potassium concentration to 3.1 mEq/L could be attributed to β_2-adrenergic activation of the Na^+–K^+ pump and subsequent transport of potassium intracellularly. In fact, high-dose albuterol via nebulizer (10–20 mg) may be used in the treatment of hyperkalemia.

Case 18-2, Question 2: What is this OTC inhaler H.T. has been using?

For decades, Primatene Mist MDI® (epinephrine) has been available in the United States as an OTC option for the temporary relief of mild asthma symptoms. In 2011, it was discontinued with other MDIs, because it contained chlorofluorocarbons (CFCs), a propellant used to deliver medication, which was deemed harmful to the environment. Although epinephrine is a known efficacious bronchodilator owing to its β-agonist properties, the increased propensity to cause adverse reactions and short duration of action makes it a poor choice as a reliever. Much to the dismay of many clinicians, Primatene Mist® reemerged in 2019 in a reformulated product containing a more environmentally friendly propellant called *hydrofluoroalkane* (HFA). In addition, Asthmanefrin® (racemic epinephrine) is available OTC in a nebulized form, which is the drug of choice in the hospital setting for stridor, and likewise should not be routinely used in the treatment of asthma. He should be counseled instead to use his ICS/formoterol as a first-line reliever.

Case 18-2, Question 3: Because of the severity of the obstruction and rapid heart rate, H.T. was monitored with an electrocardiogram (ECG) that showed sinus tachycardia alternating with SVT. Albuterol 5 mg and ipratropium 0.5 mg were given via nebulizer with little improvement. Methylprednisolone 60 mg was given via intravenous (IV) administration. H.T. was then started on 4 L of oxygen per nasal cannula to maintain O_2 saturations at 93% to 95%. PEF was now 25% of his personal best. The internal medicine resident suggests adenosine to terminate the SVT. Do you agree?

Although the treatment of SVT is beyond the scope of this chapter, the use of adenosine is not an absolute contraindication in asthma. However, H.T. has severe airway obstruction, as evidenced by his vital signs and physical exam, and the potential bronchospasm from adenosine could be disastrous in this situation. You suggest to the physician that we avoid adenosine in this case, and instead use a verapamil bolus (10 mg) and drip at 5 mg/hour. This works quickly, and his heart rhythm converts to sinus tachycardia and decreases the BP to 140/90 mm Hg.

b-Adrenergic Agonist Subsensitivity

Although tolerance or tachyphylaxis to systemic effects of β_2-agonists (eg, tremor, sleep disturbances) is documented, complete tolerance to the airway response does not occur.[43] Even with long-term use, the intensity of response to β_2-agonists is usually retained (ie, the maximal percent increase in pulmonary function), but is more pronounced in those during severe bronchoconstriction.[44] Partial tolerance has been observed with LABAs, where Haney and Hancox[45] showed a 15% lower response to albuterol after using formoterol daily for 1 week. Of note, the response to ipratropium remained unaffected. Possible explanations for patient variability include downregulation of receptors, disease progression, or true drug tolerance. The exact contribution of each is not known. Therefore, H.T.'s failure to respond to the initial therapy most likely is attributable to the severity of his airway obstruction. H.T.'s history of chronic asthma, the slow progression of this attack, and the lack of response to his inhaled β_2-agonist also are largely owing to a significant inflammatory component to this attack. Thus, bronchodilators would not be expected to immediately reverse the airway obstruction in H.T.

Case 18-2, Question 4: Repeat measurements of PEF and ABGs indicate continued significant bronchial obstruction. What should be the next step in

H.T.'s therapy?

H.T. received initial therapy with a combination of inhaled SABAs and ipratropium. He should receive a third dose of albuterol 5 mg plus ipratropium 0.5 mg 20 minutes after the second dose. Because of the severity of his exacerbation, he should then receive albuterol 15 mg/hour by continuous nebulization, with close monitoring of his cardiac status. H.T.'s PEF also should be monitored. Figures 18-11 and 18-12 outline management of asthma exacerbations in primary care and in the ED, respectively.

CORTICOSTEROIDS

Case 18-2, Question 5: Why was H.T. given IV steroids?

Corticosteroids have potent anti-inflammatory activity and are indicated in H.T.[1] In patients such as H.T. with acute asthma, corticosteroids decrease airway inflammation and increase the response to β_2-selective agonists.[46] Corticosteroids are not smooth muscle relaxants (ie, not bronchodilators); however, they can relieve bronchial obstruction by improving the responsiveness of β_2-receptors and by inhibiting numerous phases of the inflammatory response (eg, cytokine production, neutrophil and eosinophil chemotaxis and migration, and release of inflammatory mediators).[46,47]

The anti-inflammatory activity of corticosteroids is delayed for about 4 hours after the dose has been administered.[1,48] Corticosteroid-induced restoration of responsiveness to endogenous catecholamines and exogenous β_2-agonists, however, occurs within 1 hour of administration of the corticosteroid in severe, chronic, and stable patients with asthma.[1,2] Significant improvement in objective measures (eg, FEV_1) occurs 12 hours after administration. Consequently, GINA advocates early initiation of corticosteroids in cases of acute severe asthma. Corticosteroids also hasten the

recovery of acute exacerbations of asthma and decrease the need for hospitalization if given early in the initial management of acute asthma in the ED.[1,2]

On the basis of his initial presentation, H.T. should be started on systemic corticosteroid therapy immediately in the ED (see Fig. 18-12). Preferably, OCSs would have been started at home before H.T.'s exacerbation escalated to this degree of severity.

Doses of corticosteroids used to treat acute asthma are largely empiric. Studies comparing very high dosages (eg, IV methylprednisolone 125 mg every 6 hours in an adult) versus moderate dosages (40 mg every 6 hours) have shown no advantage with very high dosages.[49] In addition, oral therapy is as efficacious as the IV route.[50] Dosing recommendations for systemic corticosteroids in the management of asthma exacerbations in the ED or hospital are listed in GINA.[1] Higher corticosteroid dosages may be considered in patients with impending respiratory failure. When patients cannot take oral medication, IV methylprednisolone is preferred over hydrocortisone in patients with heart disease or fluid retention or when high dosages of corticosteroids are used; this is because it has less mineralocorticoid activity.

For patients who require IV corticosteroid therapy, the dosage can usually be reduced rapidly to 50 mg/day for adults (1–2 mg/kg/day for children) because the condition improves (usually after 48–72 hours). On discharge from the hospital, GINA recommends, for example, prednisolone 50 mg/day in one dose for 5 to 7 days.[1] Although some clinicians may prescribe a tapering regimen, no taper is necessary in this situation. On the other hand, if the patient required long-term OCS therapy before hospitalization, tapering the dose to the preadmission dosage is prudent. For patients who are discharged from the ED, up to 7 days of prednisone therapy usually is sufficient.

CASE 18-2, QUESTION 6: H.T. was given one dose of 80 mg methylprednisolone on admission to the ED about 1 hour ago and says he is feeling a bit better, yet expiratory wheezes were still audible; and he is obviously using his accessory muscles, and requires 6 L of oxygen per nasal cannula to

maintain O_2 saturations >93. His PEF was now 35% of predicted, and a repeat ABG showed $Paco_2$ of 50 mm Hg. What is the next appropriate step and how should he be monitored for impending respiratory failure?

H.T. still is significantly obstructed despite intensive therapy in the ED. As a result, he should be admitted to the intensive care unit (ICU), where he can be monitored closely.

When patients continually must expand their chest wall with high lung volumes for a prolonged period, respiratory muscle fatigue may ensue, resulting in a decreased ventilatory effort. Clinical signs of impending respiratory failure include increased heart rate, decreased breath sounds, agitation from worsening hypoxia, or lethargy from increased CO_2 retention. These clinical signs and symptoms are relatively nonspecific and are affected by many variables. Thus, they should not be used to detect impending respiratory failure.

The best way to assess therapy is to monitor ABGs. The Pao_2 component of an ABG determination is not very helpful because of $\dot{V}/\dot{Q}$ mismatching and the administration of oxygen. The $Paco_2$ is the best indicator of hypoventilation in acute asthma[2]; however, there is no single value for $Paco_2$ that indicates impending respiratory failure, because different $Paco_2$ values are acceptable under different clinical circumstances. A $Paco_2$ of 55 mm Hg 1 to 2 hours after intensive bronchodilator therapy or an increase in $Paco_2$ of 5 to 10 mm Hg/hour during aggressive therapy is an ominous sign. His slow improvement is slight but encouraging.

CASE 18-2, QUESTION 7: H.T. initially received high-dose albuterol, a total of 30 mg over 2 hours, plus standard (0.5 mg) doses of ipratropium and IV methylprednisolone 80 mg. What should we do now?

H.T.'s response to inhaled albuterol also suggests that IV β-agonists are inappropriate at this time, particularly with his recent episode of SVT. Because standard therapies already administered were not sufficient, IV magnesium sulfate may benefit severely ill

patients such as H.T.[1] Recent research has found mixed results on nebulized isotonic magnesium sulfate as an adjunctive therapy to inhaled albuterol in the treatment of severe asthma exacerbations.[51,52] Further, heliox (a mixture of helium and oxygen) may also add benefit in selected cases.[1] Should he need to be intubated, both propofol and ketamine are considered safe in asthma.

Response to therapy

Case 18-2, Question 8: H.T. has continued to improve slowly during the past 72 hours. The nebulizer treatments are now every 6 hours, and he is taking oral prednisone 60 mg once per day. PEF measurements taken before and after his last albuterol treatment were 65% and 85% of predicted, respectively. Is H.T.'s long duration of recovery unusual?

No. In a patient such as H.T., whose condition progressively deteriorated during a long period, a slow reversal should be expected. The prolonged deterioration reflects an increasing inflammatory response in the lung. These patients require prolonged, intensive bronchodilator and anti-inflammatory therapy before maximal improvement is noted in pulmonary function tests. Thus, H.T. should continue to receive systemic corticosteroids for ~7 days after such a severe acute exacerbation of asthma.[1]

Adverse Effects of Short-Term Therapy

Case 18-2, Question 9: H.T. has been taking corticosteroids for a total of 7 days. Long-term corticosteroid use is associated with many adverse effects such as adrenal suppression, cataracts, and elevated blood glucose. What adverse effects are related to short-term corticosteroid use?

Short courses of daily corticosteroids are usually associated with minor side effects.[1,2] Facial flushing, appetite stimulation, gastrointestinal irritation, headache, and mood changes ranging from

a mere sense of well-being to overt toxic psychosis are the most commonly encountered adverse effects of short-term corticosteroid therapy. Acne can be exacerbated in patients susceptible to this skin problem, and weight gain also can occur because of sodium and fluid retention. In addition, hyperglycemia, leukocytosis, and hypokalemia are possible. All of these problems are transient and will disappear with time after the corticosteroids are discontinued. These short-term adverse effects are less common when small corticosteroid doses are used; however, corticosteroid doses must be adequate to prevent disease exacerbation. The minor risks of short-term use are far outweighed by the marked benefits.

Overuse of Short-Acting b_2-Agonists

Case 18-2, Question 10: Is H.T.'s history of increased use of his albuterol during the early stages of his asthma attack appropriate?

The overuse of SABAs as a possible risk factor for asthma death has been debated for decades. Because most deaths attributable to asthma occur outside the hospital setting before the patient can reach medical assistance, the primary cause of death in asthma most probably is an underestimation of the severity of the asthma attack by the patient and delay in seeking medical help. Overuse of quick reliever medication suggests inadequate asthma control and can lead to fatal asthma. Nwaru et al in the SABA us IN Asthma (SABINA) trial conducted in Sweden found an increased mortality risk directly proportional to the number of SABA inhalers obtained per patient.[53]

Although increased use of ICS/LABA inhalers as the primary reliever is expected to decrease overall need for albuterol, as-needed albuterol is still appropriate as a second-line add-on reliever.[54] The frequency of as-needed doses of albuterol is a good marker of the adequacy of inhaled anti-inflammatory therapy and environmental control measures. For example, if the patient needs

the SABA more than once a day for 2 or 3 days per week, the clinician should reassess environmental control, increase the dose of inhaled anti-inflammatory therapy, or add other controller agents per GINA.[1] Patients should be instructed verbally and in writing regarding the proper use of their inhalers during acute attacks and in recognizing when it is necessary to seek medical assistance. Patients can continue using their short-acting β-agonist inhalers on an as-needed basis until they reach medical care. H.T. should be considered at high risk because of the severity of his latest attack, and it would be reasonable to consider providing a preemptive prescription for a 5-day OCS burst to self-administer at the first sign of significant deterioration. In addition, H.T. should have a home peak flow meter so that he can objectively determine the severity of his attacks. Finally, the β_2-agonist controversy does not extend to use of high dosages in the acute-care setting. High dosages are essential in the ED and hospital and, as discussed previously, usually are tolerated very well.

CASE 18-2, QUESTION 11: How can H.T.'s outpatient therapy be optimized?

GINA 2020 step 3 and onward recommend ICS/LABA combination therapy as the preferred controller in adults and adolescents, although step 2 still leaves daily low-dose ICS as one of the primary options as a controller, the other being ICS/formoterol as needed in place of a daily controller. Although many patients seem to be adequately controlled on a home regimen similar to H.T., Single Maintenance and Reliever Therapy, or SMART, has been proved in key trials to provide a lower risk of exacerbations as compared to traditional pharmacotherapy of persistent asthma.[42,43] These and other large studies have resulted in a "sea change" in the way patients with asthma are prescribed therapy. First, that an ICS-containing inhaler should be prescribed in all patients with asthma, regardless of symptom severity or frequency. Second, that ICS/LABA inhalers are not only safe and effective but the ICS/LABA is also an integral component of the guidelines, listed in steps 1 to 5

of GINA, with either scheduled or as-needed dosing as a controller and/or reliever. In particular, budesonide/formoterol has been studied in the majority of the trials, although there is no reason to think that mometasone/formoterol would not be equally as efficacious. However, in the United States, neither budesonide nor mometasone combined with formoterol is FDA approved yet for as-needed use. Thus, the prescribing clinician may have to attain prior authorization for H.T. for allowance of more than one budesonide/formoterol inhaler per month.

CHRONIC ASTHMA

Classification of Severity

CASE 18-3

Question 1: J.B. is a 3-year-old, 35.27-pound (16-kg) boy with a 1-year history of recurrent wheezing 3 days per week and 4 nights per month. His medications include albuterol syrup 2 mg three times per day, and albuterol MDI as needed for wheezing. J.B. demonstrates the use of his inhaler with his mother's assistance. The mother holds the inhaler in J.B.'s mouth and actuates it at the end of a deep inhalation. J.B.'s mother tells the pharmacist that he acts jittery after taking the albuterol syrup.

What is the first step in deciding how to improve J.B.'s long-term asthma treatment?

While keeping in mind the goals of therapy, the first step here is to classify J.B.'s asthma severity (see Fig. 18-3). Because J.B. has symptoms 3 days per week and 4 nights per month (persistent asthma), he should be started at step 2, and unless symptoms worsen, be reevaluated after 2 to 3 months.

Selection of Appropriate Long-Term Initial Therapy

Case 18-3, Question 2: What would be a reasonable regimen for J.B.?

According to the GINA Strategy Document 2020[1] for very young children (see Fig. 18-3), low-dose ICSs with an as-needed SABA would be the choice for J.B.[1] He could receive low-dose ICS treatments via nebulizer (budesonide) or MDI plus a spacer. Most children ages 3 years and younger cannot use dry powder inhalers because of the inability to generate sufficient peak inspiratory flow (PIF). As J.B. matures, he may be able to use some dry powder inhalers (eg, Diskus®). Oral β_2-agonists are generally not recommended because of poor tolerability attributed to increased systemic exposure compared to inhaled delivery. Because J.B. is jittery and not tolerating the albuterol syrup, it should be discontinued and replaced with an inhaled formulation. Moreover, if concurrent inhaled albuterol is administered correctly, oral albuterol is not needed and would only be expected to increase the likelihood of adverse effects. J.B.'s mother must be educated about asthma, its treatment, and the appropriate use of medications (eg, proper use of inhaler devices).

Case 18-3, Question 3: It is anticipated that because of his young age, J.B. will find it difficult to use an MDI. What alternative devices are reasonable?

Children younger than age 5 years generally have a difficult time coordinating the use of standard MDIs; therefore, the ICS and SABA should be administered by another mode of delivery. For example, the as-needed β_2-agonist and scheduled ICS could be administered with an inhalational aid ("spacer" or valved holding chamber [VHC]), which is connected to an MDI. A nebulized corticosteroid preparation (budesonide) is available for very young children. Inhalation aids significantly improve the efficacy of medications that are administered by MDI in very young children or in other patients who are unable to coordinate the plain inhalers correctly.[1,2] The AeroChamber® is a widely used VHC (the medication stays in the

chamber for a few seconds until the patient inhales slowly and the inhalation valve opens). Studies have shown that many children as young as 2 and 3 years of age can use MDIs with VHC devices by modeling after a parent.[1] VHCs with face masks are required for most children age younger than 4 years. Extender device-assisted delivery of aerosolized medications is as effective as nebulization in the home management of chronic severe asthma and even in the ED treatment of asthma in children.[1,2,38] AeroChamber® is an example of a device that contains a flow indicator whistle that sounds if the patient inhales rapidly. This whistle is particularly effective in teaching the patient the appropriate slow inhalation technique. The clinician should verify the correct use of the device by observation of the patient's or caregiver's administration technique.

Alternatively, the ICS could be administered to selected children using a breath-activated dry powder inhaler (eg, budesonide [Pulmicort Flexhaler®] or fluticasone [combined with salmeterol in Advair Diskus®]). In young children, the Diskus® has the advantage of requiring a lower PIF than does Flexhaler®, and it has been used successfully in children as young as 4 years of age.[55] Another option is the Twisthaler® used for delivery of mometasone (Asmanex®) or the breath-actuated beclomethasone (QVAR Redihaler®) inhaler, but they are approved for children ages 4 years and older.

Many pediatricians may choose a nebulizer to administer SABAs to a 3-year-old child. This method is certainly acceptable and very common, but it takes longer to administer the medication (~5–15 minutes), and the device must be properly cleaned and maintained. Because J.B. recently turned 3 years old, therapy should be initiated with nebulized budesonide (Pulmicort Respules®) in a low dose of 0.25 mg bid. As mentioned previously, GINA[1] suggests an initial trial of low-dose ICS in very young children who have not previously been treated with ICSs. The plan is to switch J.B. to a steroid inhaler approved for children at least 4 years old in 12 months, as soon as he and his caregiver can demonstrate correct use. J.B.'s clinician should assess the response to low-dose budesonide within 12 weeks. Therapy can be stepped up if necessary and subsequently

stepped down in the coming months, if possible so that optimal asthma control is achieved at the lowest ICS dose possible.

Case 18-3, Question 4: J.B.'s parents are wary of their child taking corticosteroids on a continuous basis after reading about side effects on the Internet. How should his parents be counseled?

Corticosteroids reach the systemic circulation minimally via inhalation in part because they are largely inactivated through first-pass hepatic metabolism. However, a dose-dependent response is evident, and clinically significant adverse events resulting from systemic exposure can occur, albeit more commonly with doses at the high end of the range. Long-term studies in pediatric patients have examined the effects of ICS on growth reduction, bone density, and adrenal suppression.

Although ICSs can cause a mild and temporary reduction in growth velocity, final height attained in adulthood appears to be within normal limits, although longer term trials are required to confirm these findings.[56–58] Two large studies of ICSs in pediatric patients found reductions in height of 0.47 inch (1.20 cm) to 0.52 inch (1.34 cm) when compared to placebo.[59,60] Bone density and risk of fractures have not been found in the majority of investigations to be affected by ICSs.[56,58] Although a measurable reduction in serum and urinary cortisol levels is not an uncommon finding in studies of ICSs, clinically significant adrenal insufficiency solely caused by ICSs is rare, although, again, it is more likely to occur with high doses.[56,58]

In summary, these adverse effects are generally of minimal clinical significance, with the benefits of well-controlled asthma far outweighing the risks.

The most common local side effect with ICS therapy is oropharyngeal candidiasis (thrush), but this problem is rare with any delivery system and is easily treatable with nystatin oral liquid. With MDIs, it can be further minimized using a spacer device. Rinsing the mouth with water after use of any ICSs is strongly recommended.

Another possible local side effect is hoarseness (dysphonia), and spacers may not effectively reduce this problem.

Corticosteroids in Adolescents and Adults

CASE 18-4

Question 1: S.T. is a 12-year-old girl with asthma receiving step 3 care, and has not been well controlled on inhaled mometasone monotherapy. She does admit to only using it when she feels like she needs it, but uses her as-needed albuterol multiple times per day. When her symptoms worsen, she uses her home nebulizer and awakens most nights because of wheezing. She has been hospitalized four times over the past 2 years and has required bursts of prednisone with increasing frequency. S.T. is just finishing a 2-week course of prednisone 20 mg/day. Her face has the rounded appearance of chronic oral steroid use.

What actions are needed to improve S.T.'s care?

Because S.T. is suffering needlessly and requiring frequent systemic corticosteroids, all efforts must be made to optimize other therapies and to minimize systemic corticosteroid toxicities. Although S.T. is receiving an ICS, she admits to poor adherence. Therefore, with her uncontrolled asthma, one strategy would be to increase her mometasone from medium dose to high dose, although she has already demonstrated failure of compliance with a single ICS inhaler treatment. Although short bursts of prednisone (eg, 40 mg/day for 3 days) are very helpful occasionally, frequent short courses often indicate the need to optimize other therapies. Some patients require courses of 1 to 2 weeks. S.T. is requiring longer frequent bursts and is showing signs of adverse effects. Obviously, S.T. and her parents also need a concerted and persistent effort in patient education as a partnership (refer to the sections Patient Education and Outcomes).

ICSs are chemically modified to maximize topical effectiveness while minimizing systemic toxicities. GINA[1] compares the dosages of ICS products. These differences in dosages (low, medium, and high) reflect differences among ICSs in receptor-binding affinity and topical potency. There are also differences among these agents in oral

bioavailability (ie, absorption of drug that is swallowed after inhalation) and systemic availability via absorption from the lungs. Of these two variables, absorption from the lungs is the most likely contributor to possible hypothalamic–pituitary–adrenal (HPA) suppression or other systemic effects. Fortunately, the total absorption has not been shown to be clinically important, except at the higher recommended dosages. Although the various ICSs are not equipotent on a microgram-per-microgram basis, major differences in efficacy or adverse effects are not firmly established (**Table 18-2**).[1,2] For patients with severe-persistent asthma, a logical choice would be a high-potency agent that would allow for a minimum number of inhalations per day, potentially improving treatment adherence. Furthermore, the delivery system used affects pulmonary deposition, but each available delivery system has established efficacy if used correctly. The differences among the various dry powder inhalers are discussed later in this chapter. Addition of a spacer device to an MDI also enhances pulmonary deposition. In very high dosages (the equivalent of 1600 µg/day of beclomethasone dipropionate), all ICSs produce some degree of HPA axis suppression.[2] The clinical significance of this suppression has yet to be firmly established.

Table 18-2
Low, Medium, and High Daily Doses of Inhaled Corticosteroids

This is not a table of equivalence, but, instead, suggested total daily doses for the "low-," "medium-," and "high-" dose ICS options for adults/adolescents, p. 54 and children 6–11 years, p. 55, based on available studies and product information. Data on comparative potency are not readily available and, therefore, this table does *not* imply potency equivalence. Doses may be country specific depending on local availability, regulatory labeling and clinical guidelines.

Low-dose ICSs provides most of the clinical benefit of ICS for most patients with asthma. However, ICS responsiveness varies between patients, so some patients may need **medium-dose ICS** if their asthma is uncontrolled despite good adherence and correct technique with low dose ICS (with or without LABA). High dose ICS (in combination with LABA or separately) is needed by very few patients, and its long-term use is associated with an increased risk of local and systemic side-effects, which must be balanced against the potential benefits.

Adults and adolescents (12 years and older)			
Inhaled corticosteroid	*Total daily ICS dose (μg)—see notes earlier*		
	Low	*Medium*	*High*
Beclometasone dipropionate (pMDI, standard particle, HFA)	200–500	>500–1000	>1000
Beclometasone dipropionate (pMDI, extrafine particle[a], HFA)	100–200	>200–400	>400

Fluticasone propionate (pMDI, standard particle, HFA)	50–100	>100–200	>200
Mometasone furoate (pMDI, standard particle, HFA)	100		200

DPI, dry powder inhaler; HFA, hydrofluoroalkane; ICS, inhaled corticosteroids; LABA, long-acting β-agonist; n.a., not applicable; pMDI, pressurized metered-dose inhaler.

[a] See product information.

Source: Gina.org. Accessed October 4, 2020. https://ginasthma.org

Although low-to-moderate dosages of ICSs are accepted as being quite safe, very high dosages continue to be scrutinized regarding the potential adverse effects.[1] Clearly, for patients who require high dosages for optimal control of asthma, the benefits of therapy with these agents far outweigh the risks.[1,2] A possible association between prolonged, very high dosages of ICSs and cataracts[61] and glaucoma[62] has been reported.

All of these risks seen with ICSs are greatly outweighed by the benefits. In a landmark study, Suissa et al demonstrated a decreased mortality rate examining ICS usage over several years in

>30,000 patients. Remarkably, this trial demonstrated a dose–response curve, which is a proportional decrease in mortality rate with each increasing number of ICS canisters used.[63]

Case 18-4, Question 2: How should S.T. be managed?

LABAs have been very successful in the prevention of "stepping up" the dose of ICSs while markedly enhancing overall asthma control, and this fact is reflected in GINA.[1,64] S.T.'s care level is escalated to step 4, and a reasonable therapeutic option for would be the combination of fluticasone 250 µg and salmeterol 50 µg via Diskus® (Advair 250/50®) one inhalation bid, the budesonide/formoterol (Symbicort®) combination inhaler (160 µg/4.5 µg) two inhalations bid, the mometasone/formoterol (Dulera®) combination inhaler (100 µg/5 µg) two inhalations bid daily. Airduo Digihaler® 113/14 µg one inhalation bid. S.T. should be reevaluated in 2 weeks. Wanting to ensure adherence and engage S.T. in the treatment plan, her physician suggested a new "smart" "inhaler. S.T. was excited to use this Airduo Digihaler® (fluticasone/salmeterol) because it involved using an application on her smartphone that tracks data including compliance and inspiratory flow rates, which is available for both her and her doctor to analyze. The plan is to step down the dose of fluticasone after excellent asthma control is achieved.

Adverse effects associated with long-acting inhaled a_2 agonists

Case 18-4, Question 3: S.T.'s parents researched their daughter's new type of medicine and found reports of fatalities associated with a very similar inhaler on the Internet. How would you educate them?

Several randomized trials[65] for more than a decade have demonstrated that LABAs have minimal adverse effects (eg, tachycardia, tremor). EPR-3[2] and GINA[1] both strongly recommend against the use of LABAs as monotherapy for long-term control of

persistent asthma. LABA therapy should only be used in the form of a combination ICS/LABA inhaler, never as separate inhalers in patients with asthma. There were previous safety concerns stemming from a signal of increased deaths from the SMART study,[66] which investigated adding salmeterol to baseline treatment, which did not always include ICSs. More recently, a meta-analysis involving over 36,000 patients enrolled in head-to-head trials of ICSs versus ICS/LABA found both a lower risk of asthma exacerbations and only two deaths in the ICS/LABA arm.[67] Based on these results, an ICS/LABA therapy is preferred for S.T.

Case 18-4, Question 4: After being adherent to her new therapy for 1 month, one inhalation twice daily of fluticasone 113 µg/14 µg salmeterol, S.T.'s asthma control has markedly improved. She has required no ED visits, sleeps through the night, and has started exercising outside again. Her PEF is staying near at least 90% of her personal best and uses her albuterol inhaler less than once per week. At the 6-month mark, with continued excellent control of symptoms, her clinician is ready to step down the dose. How does she proceed in a safe manner?

GINA[1] suggests stepping down the dose at a rate of 25% to 50% every 3 months to the lowest dose that maintains control (**Table 18-3**). A step down to fluticasone 55 µg/salmeterol 14 µg would be a reasonable reduction in therapy for S.T. If a single ICS product had been started for S.T. initially (eg, budesonide, beclomethasone, fluticasone), the dosage reduction would normally proceed at a slower pace. However, fluticasone 50 µg bid, especially in combination with salmeterol, will likely be an adequate dose for S.T. After S.T.'s dose of fluticasone was stepped down as planned, she started requiring only slightly more prn albuterol (but still was symptom free most days).

Table 18-3
Options for Stepping Down Treatment Once Asthma Is Well Controlled

General Principles of Stepping Down Asthma Treatment

- Consider stepping down when asthma symptoms have been well controlled and lung function has been stable for ≥3 months (Evidence D). If the patient has risk factors for exacerbations (Box 2-2, p. 35), for example, a history of exacerbations in the past year,[271] or persistent airflow limitation, do not step down without close supervision.
- Choose an appropriate time (no respiratory infection, patient not traveling, not pregnant).
- Approach each step as a therapeutic trial. Engage the patient in the process; document their asthma status (symptom control, lung function, and risk factors, Box 2-2, p. 35); provide clear instructions; provide a written asthma action plan (Box 4-2, p. 117) and ensure the patient has sufficient medication to resume their previous dose if necessary; monitor symptoms and/or PEF; and schedule a follow-up visit (Evidence D).
- Stepping down ICS doses by 25%–50% at 3-month intervals is feasible and safe for most patients[277] (Evidence A).

Current Step	Current Medication and Dose	Options for Stepping Down	Evidence
Step 5	High-dose ICS–LABA plus OCSs	■ Continue high-dose ICS–LABA and reduce OCS dose ■ Use sputum-guided approach to reducing OCS ■ Alternate-day OCS treatment ■ Replace OCS with high-dose ICS	D B D D
	High-dose ICS–LABA plus other add-on agents	■ Refer for expert advice	D
Step 4	Moderate- to high-dose ICS–LABA maintenance treatment	■ Continue combination ICS–LABA with 50% reduction in ICS component by using available formulations. ■ Discontinuing LABA may lead to deterioration.[278]	B A
	Medium- to high-dose ICS–formoterol[a] as maintenance and reliever	■ Reduce maintenance ICS–formoterol[a] to low, and continue as-needed low-dose ICS–formoterol[a] reliever.	D
	High-dose ICS plus second controller	■ Reduce ICS dose by 50% and continue second controller.[227]	B
Step 3	Low-dose ICS–LABA maintenance	■ Reduce ICS–LABA to once daily. ■ Discontinuing LABA may lead to deterioration.[278]	D A
	Low-dose ICS–formoterol[a] as maintenance and reliever	■ Reduce maintenance ICS–formoterol[a] dose to once daily and continue as-needed low-dose ICS–formoterol[a] reliever.	C
	Medium- or high-dose ICS	■ Reduce ICS dose by 50%.[277] ■ Adding LTRA[b] may allow ICS dose to be stepped down.[279]	A B
Step 2	Low-dose ICS	■ Once-daily dosing (budesonide, ciclesonide, mometasone)[280,281] ■ Switch to as-needed low-dose ICS–formoterol.[171,177,180] ■ Switch to taking ICS whenever SABA is taken.[184,185,187]	A A B
	Low-dose ICS or LTRA	■ Switch to as-needed low-dose ICS–formoterol.[173,174,177,180] ■ Complete cessation of ICS in adults and adolescents is not advised because the risk of exacerbations is increased with SABA-only treatment.[276]	A A

BDP, beclometasone diproprionate; ICS, inhaled corticosteroid; LABA, long-acting β_2-agonist; LTRA, leukotriene receptor antagonist; OCS, oral corticosteroid; SABA, short-acting β_2-agonists.

[a]ICS–formoterol maintenance and reliever treatment can be prescribed with low-dose budesonide–formoterol.

[b]Note U.S. Food and Drug Administration (FDA) warning on neuropsychiatric effects with montelukast.[205]

CASE 18-4 QUESTION 5: What education should be done with S.T. and her parents during this clinic visit?

S.T. needs to hear from the clinicians treating her that asthma does not have to dominate her life, and in the words of a title to an NIH booklet for patients, “Your asthma can be controlled: Expect

nothing less." Finally, special care should be taken in cleaning the MDI actuator. Health care professionals should stress the importance of regular MDI actuator cleaning with their patients. S.T. needs a written asthma action plan and an emergency supply of prednisone (ie, to use when her PEF is in the red zone and unresponsive to the reliever).

During follow-up evaluations, clinicians should carefully investigate factors that may contribute to poor asthma control, including exposure to inhalant allergens, indoor or outdoor irritants, medications, and tobacco smoke. Secondhand smoke exposure has been demonstrated to reduce the benefit of ICSs in children and necessitate step-up therapy, and patients with asthma who smoke have reduced response to ICS therapy.[68]

Leukotriene Modifiers

CASE 18-5

QUESTION 1: C.R. is a 53-year-old male with asthma and dysthymia (persistent depressive disorder) requiring step 2 treatment for his asthma. His asthma symptoms began when he was 2 years old, and he has never smoked. C.R. has had numerous drug regimens for his asthma over the years and would like to try life without inhalers. His coworker only takes a pill for his asthma, so C.R. would like to try that out as well, or, at the very least, minimize his reliance on inhalers.

Is this appropriate for C.R.?

In patients of any age with GINA step 2 asthma, and certainly in children or adolescents, an oral agent such as montelukast with once-daily dosing at bedtime has obvious advantages. Zileuton® is another leukotriene modifier, but it has more drug interactions and adverse effects than do the other available agents. A daily low-dose ICS or as-needed ICS/formoterol is the preferred treatment for step 2 asthma. Studies comparing ICSs with leukotriene receptor agonists have consistently demonstrated the superiority of ICSs for most asthma outcome measures,[69–71] but in patients (adults or children) who prefer oral therapy to inhaling medication every day, leukotriene

modifiers are a reasonable option. The simplest and safest possible oral controller regimen for C.R. is montelukast 10 mg at bedtime (with prn inhaled ICS/formoterol as the reliever). Bedtime dosing with montelukast is recommended because it will have peak activity late at night and in the early morning hours when asthma symptoms tend to be more frequent. However, montelukast has a boxed warning for the development of agitation, depression, and suicidal ideation, so he must be counseled carefully and agree to close monitoring for neuropsychiatric effects with his prescriber and counselor.[72] It is likely that this regimen will result in good asthma control. If C.R. does not have good control of his asthma when he returns to the clinic in a few weeks, switching to a low-dose ICS in the evening only would keep the regimen simple while enhancing efficacy.

Anticholinergics

CASE 18-6

QUESTION 1: N.C. is a 25-year-old musician with asthma requiring step 4 treatment, which has been controlled well for the past 3 years on Advair® (fluticasone propionate/salmeterol). Recently he has noticed that his asthma symptoms have worsened, he is requiring his albuterol inhaler three to four times per week, and frequently awakens feeling tightness in his chest, which is improved for a few minutes after a hot shower. He sees an online commercial for a new type of inhaler that contains three different medicines.

He comes to your clinic and asks if this new drug is “right “for him. How do you respond?

Until the past few years, antimuscarinic agents have had limited use in asthma except for ipratropium in the ED and have been used for COPD almost exclusively. However, in 2012, Kerstjens et al in a randomized, controlled trial found that tiotropium, a long-acting antimuscarinic agent (Long Acting Muscarinic Antagonist, LAMA) added to combination ICS/LABA once daily in patients with suboptimally controlled adult asthma was superior to placebo.[73] Subsequently, in patients with persistent asthma poorly controlled on

ICSs, researchers demonstrated that the addition of tiotropium to ICS therapy was noninferior to the effects of adding salmeterol to ICS therapy and was superior to doubling the inhaled steroid dose.[74] The morning and evening PEFs were significantly higher in patients receiving tiotropium than in those receiving a doubling of the ICS dose.[74] Now an option per GINA for step 4 treatment, a therapeutic trial of LAMA, perhaps even with the inhaler N.C. saw in the commercial, may be considered given these new data. In 2015, Spiriva Respimat® was approved for use as maintenance therapy in patients with asthma and is now approved in both adults and in children ages 6 years and older. Both GINA[1] and the NIH[16] guidelines position LAMA as an add-on treatment for those who remain symptomatic despite already receiving combination ICS/LABA treatment (**Fig. 18-13**). However, it must be noted that LAMA use in asthma should always be given in conjunction with ICSs. The (in) *A*ppropriate *L*AMA *P*rescribing in *A*sthma patients: A *C*ohort *A*nalysis (ALPACA) trial, an observational study that evaluated LAMA use in patients with asthma, revealed a significant increase in severe asthma exacerbations when a LAMA was used as monotherapy.[75] Trelegy Ellipta® (fluticasone furoate/umeclidinium/vilanterol) is another antimuscarinic-containing inhaler that FDA approved in 2020 for asthma in patients at least 18 years old. Although there are several inhalers containing LAMAs on the market, only a few are FDA approved for use in asthma at this point. Given his suboptimal asthma control despite good adherence and proper technique, the clinician decides to prescribe Trelegy® 100/62.5/25 µg once daily for N.C.

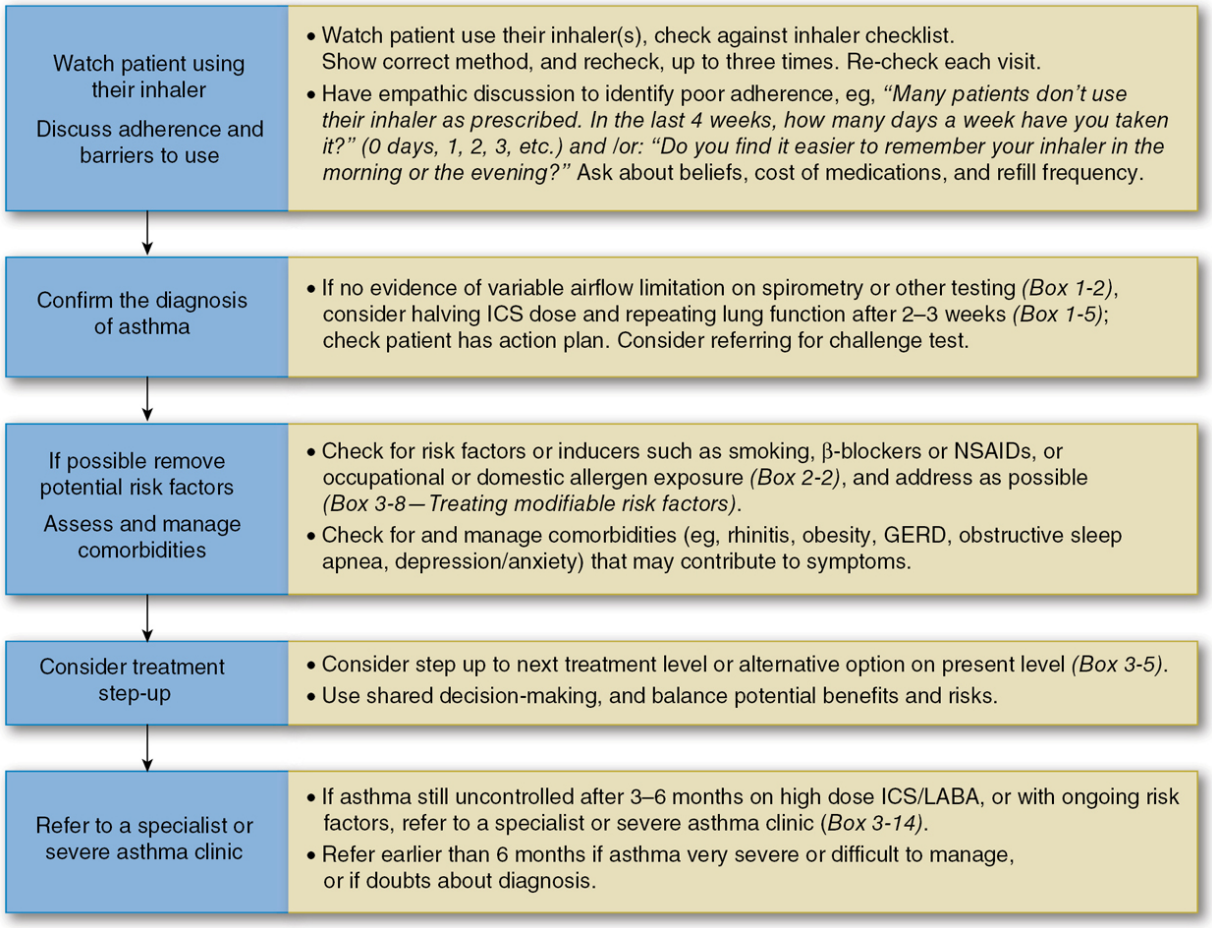

Figure 18-13 Investigating a patient with poor system control and/or exacerbation despite treatment.

Biologics

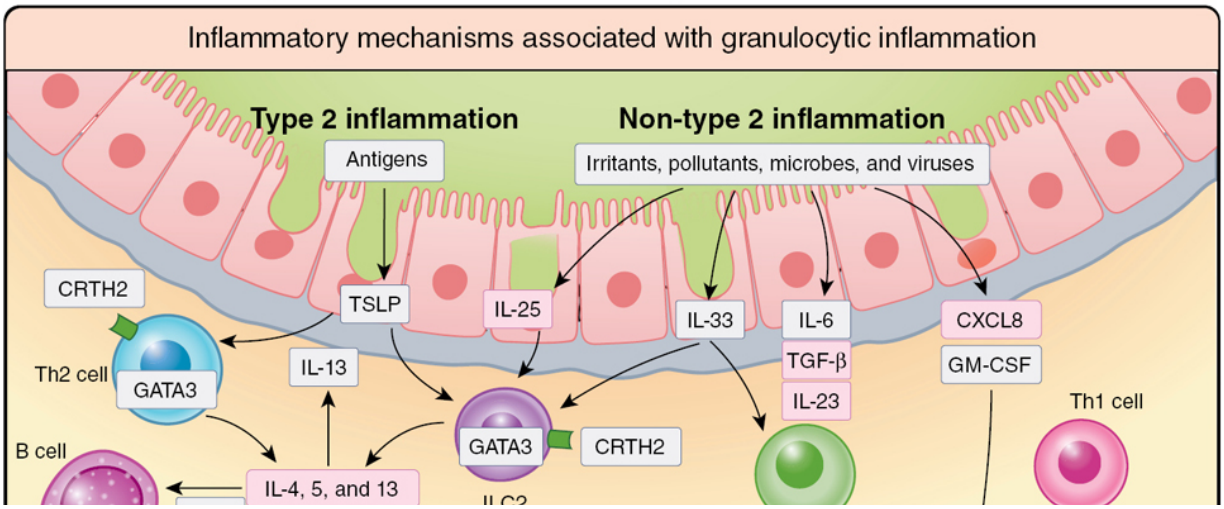
CASE 18-7

QUESTION 1: M.M. is a 30-year-old female with asthma requiring step 5 treatment who has been worsening on ICS/LABA/LAMA and environmental control around her house and workplace. In addition, she suffers from both nasal polyps and chronic rhinosinusitis, which are more prevalent in patients with asthma. She has had two recent and frightening hospitalizations for asthma. Her allergist ordered a blood eosinophil count, which is reported at 325 cells/μL, whereas FeNO was measured at 27 ppb. She is considering one of the asthma biologic treatment options in an effort to improve her quality of life and to prevent her from going on chronic OCSs.

How should she proceed in selecting from the currently available drugs?

Currently, there are five available injectable biologic (monoclonal antibody) drugs for asthma, which, at this point, are typically employed only in patients with severe asthma who are refractory to standard GINA step 5 therapies (high-dose ICS/LABA ± LAMA, low-dose OCSs). Most of the efficacy observed with the biologics likely stems from their actions blocking eosinophilic-mediated inflammation (**Fig. 18-14**). At the time of this writing, there have been no head-to-head randomized trials comparing these agents directly. In addition, because many of these drugs tend to perform better in patients with a higher baseline level of eosinophils, for most situations it is unclear which of these drugs should be tried first in a given patient, although FDA-approved indications vary slightly.[22,76] Until more evidence becomes available, the use of these very expensive agents is, in large part, determined by insurance coverage and physician preference. Because this area of asthma research is proceeding at a rapid rate and is highly specialized, GINA and the joint ERS and ATS both publish separate focused guidelines on difficult-to-treat/severe asthma.[15,77] Omalizumab was the first of these drugs available. It inhibits the binding of IgE to receptors on the surface of mast cells and basophils, reducing the activation of these cells, thereby preventing the release of proinflammatory mediators that are key components in most types of asthma.[78] It is administered 75 to 375 mg SC every 2 to 4 weeks depending on age, weight, and pretreatment IgE level.

Inflammatory mechanisms and pathobiologic features leading to severe asthma



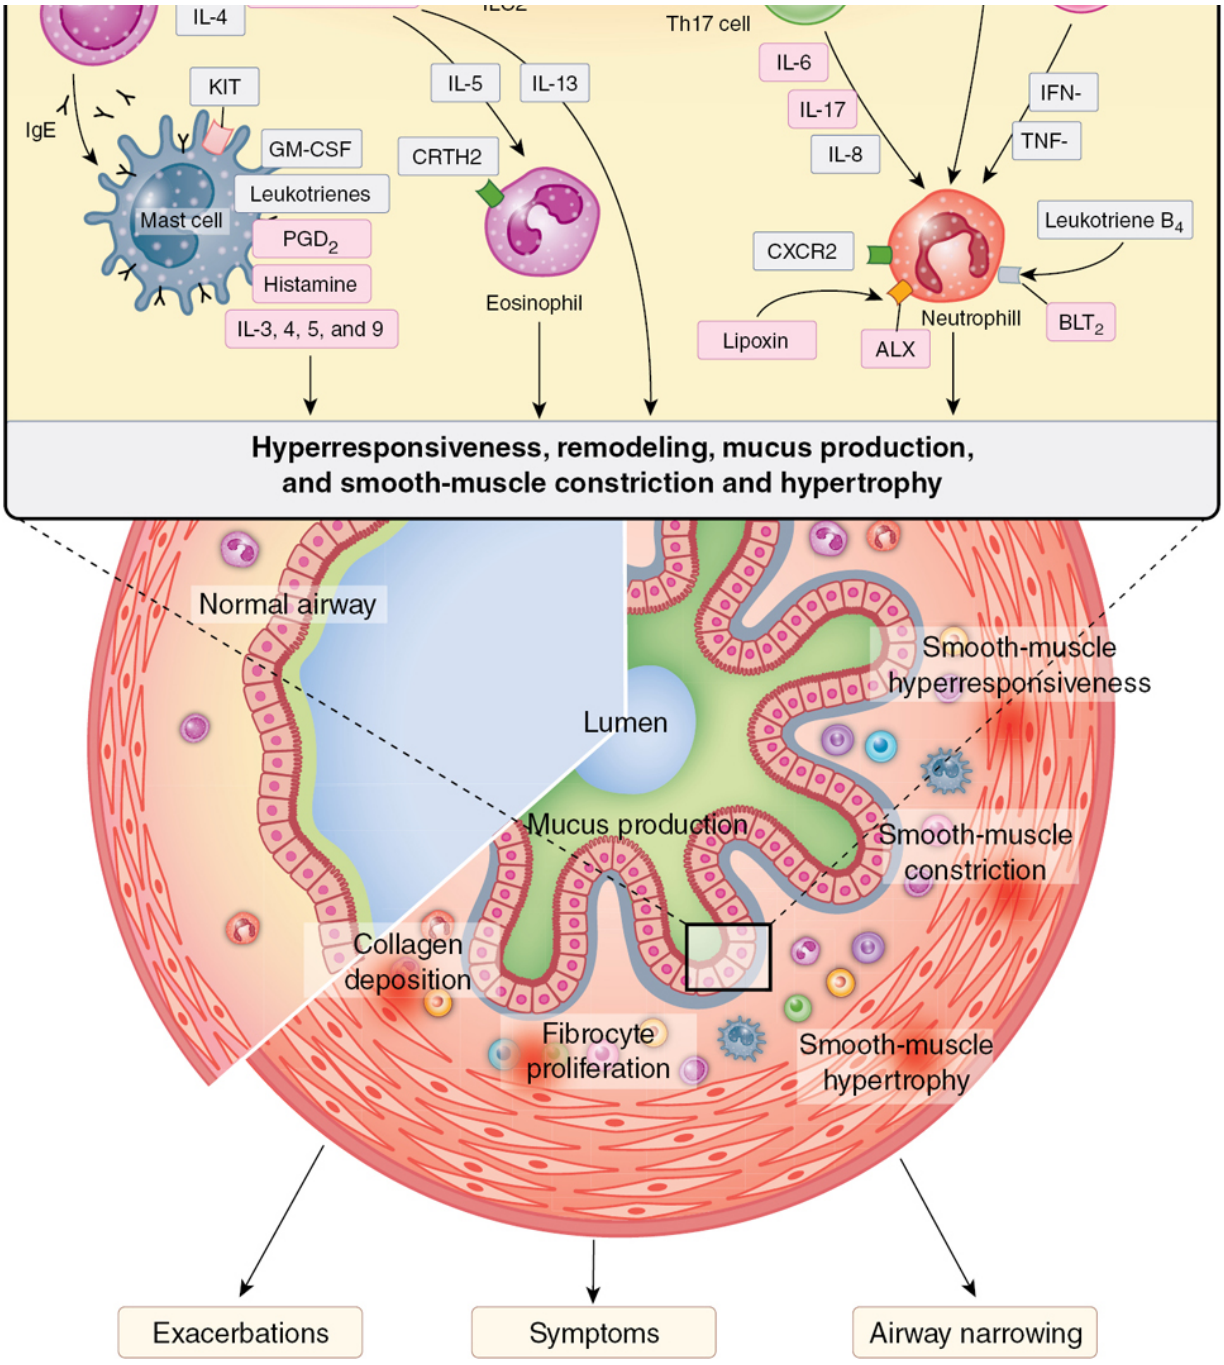


Figure 18-14 Inflammatory mechanisms and pathobiologic features leading to severe asthma (From Israel E, Reddel HK. Severe and difficult-to-treat asthma in adults. *N Engl J Med*. 2017;377(10):965–976. © 2017 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

There are three drugs that primarily affect interleukin (IL)-5. This cytokine plays an essential role in signaling, function, and recruitment of eosinophils to the airway, leading to inflammation.[6,11,79] Mepolizumab,[80] an IL-5 antagonist, is dosed at 40 mg SC every 4 weeks (ages 6–11 years) or 100 mg SC every 4 weeks (ages 12 years and older). Reslizumab,[81] an IL-5 antagonist, is dosed at 3 mg/kg actual body weight IV over 20 to 50 minutes every 4 weeks.

Benralizumab[82] binds to the α-subunit of the human IL-5 receptor, which is found on the surface of eosinophils and basophils. This activity not only prevents the interaction of IL-5 with the receptor but also results in apoptosis of these same cells. It is FDA approved for self-administration at home. The initial dose is 30 mg SC every 4 weeks in three doses; thereafter, the dose is 30 mg SC every 8 weeks.

Dupilumab[83] is an IL-4 receptor α-antagonist that binds to the IL-4 α-subunit shared by both IL-4 and IL-13, inhibiting multiple inflammatory cells that express IL-4 receptors. It is FDA approved for self-administration at home. The dose is 400 SC in one dose, then 200 mg SC every 2 weeks or 600 mg SC in one dose, then 300 mg SC every 2 weeks if the patient is on oral steroids or has moderate-to-severe atopic dermatitis.

Dupilumab is chosen for M.M. because it is also FDA approved for chronic rhinosinusitis with nasal polyps, for which M.M. has also been unsuccessfully treated for several years. Because it is a 2-hour round trip to her doctor's office, the added convenience of self-administration of the drug at home makes it a practical choice for her.

EXERCISE-INDUCED BRONCHOCONSTRICTION

CASE 18-8

QUESTION 1: J.Z. is a 35-year-old male who presents to the clinic with a history of severe coughing and chest tightening after exercise. He has recently tried to step up his weekend running to enrolling in 5K events but becomes symptomatic half way through the race.

Why is this happening?

Exercise-induced bronchoconstriction (EIB) is mostly present in those with a diagnosis of asthma but can occur in normal subjects as well. During sustained exercise, at least 90% of patients with asthma experience an initial improvement in pulmonary function quickly followed by a significant decline (**Fig. 18-15**). This phenomenon may be the only symptom of subclinical asthma.[84] Patients can be diagnosed by measuring the FEV_1 or PEF before and after exercise (6- to 8-minute treadmill or bicycle exercise test). A reduction in FEV_1 by >15% of the baseline value is a positive test result.[83,84]

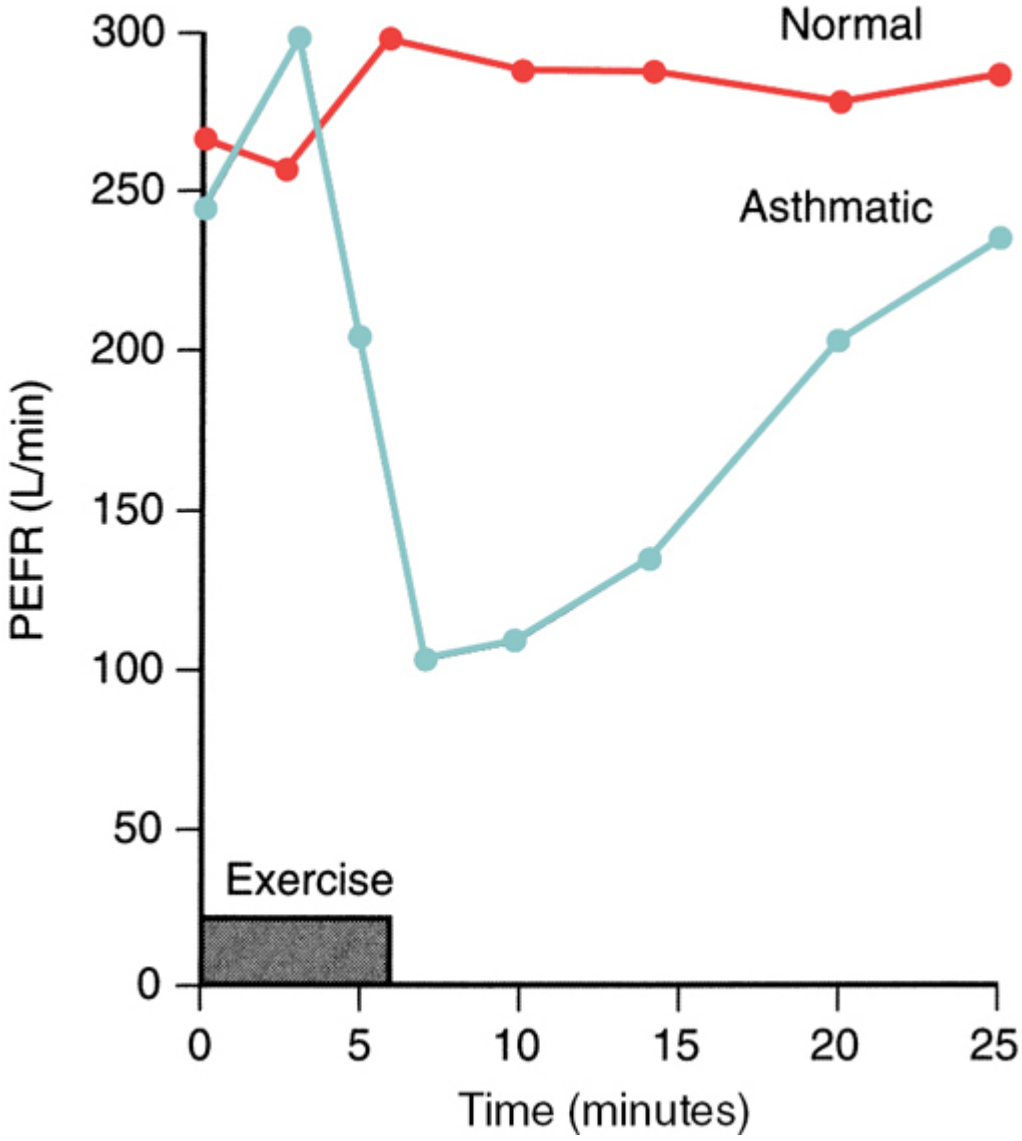

Figure 18-15 Changes in peak expiratory flow rate with exercise in a patient with asthma and a normal subject. PEFR, peak expiratory flow rate.

Hyperventilation of cold, dry air increases the sensitivity to EIB and induces bronchospasm.[84,85] The main stimulus for EIB is respiratory heat loss, water loss, or both, whereas breathing heated, humidified air completely blocks exercise-induced asthma (EIA) in many patients.[85] Masks are indicated for patients with EIA in the wintertime, and patients with severe asthma accompanied by EIB also should be encouraged to engage in other indoor exercises that do not promote EIB. A warm-up period before strenuous exercise is

helpful in some patients. With appropriate premedication, most EIB can be prevented, so virtually all patients with stable asthma should be encouraged to exercise. The mechanism of bronchoconstriction after airway heat and water loss is still incompletely understood.

Case 18-8, Question 2: What is the best course of action?

Although warming up at least 15 minutes before exercise and attempting to primarily breathe through the nose or through a scarf to warm up the inspired air may help to some degree, pharmacotherapy is the mainstay of prevention and treatment, with β-agonists playing the primary role.

About 15 minutes before exertion, either albuterol, two puffs (180 µg) or one to two puffs of formoterol-containing inhaler are highly effective in preventing significant bronchoconstriction.[85] Although any LABA-containing inhaler would be expected to work if administered at the appropriate time relative to its particular onset of action, formoterol has a faster onset of action compared to other LABAs, so it would be a reasonable choice to use either a mometasone/formoterol or budesonide/formoterol MDI at least 15 minutes before exercising. The duration would be expected to be ~10 to 12 hours with formoterol.

Other Treatments

Montelukast carries a specific indication for prevention of EIB in patients ages 6 years and older, and 5 to 10 mg (pediatric and adult doses, respectively) taken 2 hours before exercise produces a measurable but modest effect in preventing EIB. For example, Raissy et al[86] reported that EIB was prevented in 100% of the pediatric patients receiving albuterol compared with 55% receiving montelukast.

Chromones, which are mast cell stabilizers, can also be used in the prevention of EIB, but the duration of prevention is short (2–3 hours).[87] Cromolyn sodium 20 mg/2 mL nebulized solution is the only

available inhaled option from this class and should be administered 1 hour before exercise or exposure to other precipitating factors. As a controller, it needs to be taken four times per day, so consequently its overall use has fallen out of favor, making it a less attractive option.

J.Z. is prescribed mometasone/formoterol two puffs 15 minutes before exercise because this is the product on his health plan's formulary. Although this product is not specifically FDA approved for this use, he ends up using less than one inhaler per month, so his insurance company does not refuse to cover it in this situation.

CASE 18-8, QUESTION 3: Will EIB prevent J.Z. from becoming a successful 5K competitor?

No. Although J.Z. may not win any gold medals or pick up any contracts from athletic shoe manufacturers, it is not because of his EIB. There are many examples of world-class, elite athletes who have asthma and/or EIB that have competed successfully in both the Olympics and on professional sports teams such as David Beckham, Michael Phelps, and Jackie Joyner Kersee, to name just a few.

DRUG-INDUCED ASTHMA

The clinician should counsel the patient regarding the fact that patients with asthma who are aspirin sensitive often react to other nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen by developing asthma symptoms with the first dose. The health care professional should suggest acetaminophen. If J.Z. says that acetaminophen does not give adequate relief of his pain, other options are salsalate or consultation with a board-certified allergist with experience in aspirin and NSAID desensitization. The clinician should also suggest consultation with an allergist regarding evidence that cyclooxygenase (COX)-2 inhibitors are safe in aspirin-sensitive asthma for a particular patient.[88] This case also points out the need

for health professionals to pay close attention to patient use of nonprescription medications. Although drug-induced asthma may present as relatively mild symptoms in some patients, fatal asthma caused by medicinal agents has been reported numerous times. The most extensive literature on drug-induced asthma involves NSAIDs and β-blockers. Other drugs and drug preservatives also can induce symptoms of asthma, but because the topic is beyond the scope of this chapter, the reader is referred to other sources[89–91] for further discussion.

The percentage of patients with asthma reported to have aspirin exacerbated respiratory disease ranges from 4% to 28%.[89–91] Clinical manifestations of aspirin sensitivity include rhinorrhea, mild wheezing, or severe, life-threatening shortness of breath. Once the reaction has occurred, there is a refractory period of 2 to 5 days.[90] If a patient with asthma is aspirin sensitive, it is likely that the patient also will react to most other NSAIDs. Aspirin and other NSAIDs share common mechanisms involving the arachidonic acid pathways, including inhibition of COX, which results in more rapid synthesis and overproduction of leukotrienes.[89–91] Montelukast has been found to at least be partially effective in blocking aspirin-induced asthma.[92] Because most patients with asthma do not react to aspirin and other NSAIDs, the NIH guidelines recommend avoiding these agents only in patients with known sensitivity.[2] In addition, patients with severe-persistent asthma or nasal polyps should be counseled regarding the risks associated with these drugs. In patients with known sensitivity, acetaminophen or salsalate is recommended for headaches and relatively minor pain.[2] For patients who are sensitive but who need to take aspirin (eg, after myocardial infarction [MI]) or an NSAID (eg, arthritis), it is possible to desensitize the patient, and daily use then prevents further reaction.[88] Prostaglandin D_2, one of the key mediators, is produced by eosinophils in aspirin-exacerbated disease.[93,94] Likewise, it has been noted that some of the biologics, omalizumab in particular, have resulted in the reversal of aspirin intolerance.[95,96] Although not as thoroughly studied, it has been noted in surveys that a significant

percentage of patients with asthma experience alcoholic drinks as a trigger.[97] In a small trial looking at alcohol sensitivity in asthma, 75% of the subset of patients with aspirin-exacerbated respiratory disease was found to have upper respiratory tract reactions with alcohol.[98]

When discussing drug-induced asthma, the other major consideration is β-blockers. These agents should be used with great caution in patients with asthma. Because even β_1-adrenergic blockers lose selectivity as dosages are increased, they, as well as nonselective β-blockers, should be avoided in most patients. Furthermore, ophthalmic timolol has been reported several times to cause fatal asthma, and should absolutely be avoided in patients with a history of asthma.[99] Other β-blocker eye drops (eg, betaxolol) have been reported to have less propensity to induce asthma, but all have some risk.[100,101]

Two notable exceptions to using β-blockers in patients with asthma are patients who are post-MI and patients with heart failure. Because β-blockers prolong life after an MI and improve the care of patients with heart failure, benefits versus risks should be weighed. Risks outweigh benefits if a patient has severe-persistent asthma. If a post-MI patient has intermittent asthma or well-controlled mild-to-persistent or moderate-to-persistent, asthma with optimal management, a low dosage of metoprolol is a reasonable consideration in which benefits may outweigh risks, with safe titration to goal dose. If the indication is hypertension, atenolol is another option and can be started at 50 mg/day, although, again, full benefits are not attained until the dose is adjusted to a goal BP. Patients with asthma have been shown to respond to inhaled β_2-agonists when receiving this dosage of atenolol.[102] For patients with heart failure, metoprolol controlled release/extended release (CR/XL) is the cardioselective β-blocker approved in the United States, whereas carvedilol, which has nonselective β-blocker as well as α-blocking properties, can worsen asthma symptoms or cause fatal asthma. A recent population-based nested case-control study comparing cardioselective β-blockers to non–cardioselective β-blockers in patients with asthma found that cardioselective β-blockers

prescribed to people with asthma and cardiovascular disease (CVD) were relatively safe and not associated with a significant increase in asthma exacerbations.[103] However, the authors did find both an overall increase in exacerbations and a dose–response effect of asthma exacerbations with non–cardioselective β-blockers, with exacerbations being more likely to occur with higher dosages.[103]

NOCTURNAL ASTHMA

CASE 18-9

QUESTION 1: R.R., a 41-year-old male, presents to the clinic with a history of coughing and shortness of breath and stuffy nose that awakens him virtually every night. Diagnosed with asthma in elementary school that has not bothered him much until recently, he is on step 1 treatment with low-dose ICSs taken whenever albuterol is taken as needed, although because he feels better instantly after the albuterol, he often fails to use the ICS. R.R.'s morning PEF is consistently in the yellow zone, usually about 400 L/minute (personal best of 600 L/minute), whereas in the early evening his PEF is consistently just <600 L/minute.

What is the next step?

Many patients with asthma experience symptoms that awaken them in the night or occur on awakening in the morning. Morning cough with or without bronchospasm may be a clue to nocturnal asthma. Although nocturnal asthma may be appropriately viewed as simply another manifestation of airway inflammation, it is so common and troublesome among patients with asthma that it deserves special note. When it occurs with any regularity, it is an indication that the asthma is not under control. Circadian rhythm in PEF is exaggerated in patients with asthma. The difference in PEF in normal subjects averages about 8% between 4 PM (maximal airflow) and 4 AM (minimal airflow), but in patients with asthma, the average variation can be as high as about 50%.[104] Several mechanisms account for this diurnal variation in PEF. The following are examples

of factors that contribute to nocturnal asthma: increased release of inflammatory mediators, increased activity of the parasympathetic nervous system, lower circulating levels of epinephrine, and lower levels of serum cortisol (lowest at about midnight).[104] In addition, for patients whose asthma is triggered by gastroesophageal reflux, this problem is worse at night, but treatment of this problem generally provides only minimal improvement in asthma management.[104]

The initial approach to managing nocturnal symptoms is the same as that for overall long-term therapy of persistent asthma, including adequate anti-inflammatory agents.[1,2] ICSs are often effective in eliminating or reducing nocturnal asthma, including symptoms and the drop in PEF. Also, the basic asthma treatment principle of good control of concomitant rhinitis and environmental control, especially in the bedroom (eg, house dust mites, household pets), should be considered in the patient with nocturnal asthma symptoms.

Because asthma is primarily an inflammatory disease and nocturnal symptoms are largely caused by airway inflammation, the first concern in R.R. is that he needs significant modifications to his regimen. By getting R.R. to change his regimen to 180 µg of budesonide (Pulmicort Flexhaler®) twice per day and switch to as-needed ICS/formoterol as the reliever (increasing his level of care to step 2), this is likely enough anti-inflammatory activity to prevent his nocturnal symptoms and provide adequate control throughout the day. Adding a daily dose of a nonsedating antihistamine (such as 10-mg loratadine or cetirizine, 5 mg of levocetirizine, or 180 mg of fexofenadine) may help with his rhinitis.

As part of optimal management of nocturnal asthma, R.R. also should be asked about avoiding or minimizing exposure to his asthma triggers (eg, if he is allergic to dogs, are there dogs in the bedroom?). Follow-up visits for R.R. should verify that the early morning and evening PEFs remain in the green zone and that symptoms, both during the night and on awakening in the morning, have been eliminated.

PATIENT EDUCATION

If optimal long-term drug therapy of asthma is prescribed, treatment may still fail or be suboptimal if the patient does not receive adequate education. Patients with asthma require special educational efforts because of the use of inhalation devices and peak flow meters. In addition, it often is a major challenge to have patients and parents understand the critical importance of long-term daily controller therapy and environmental control. Of course, an important first step in educating patients with asthma is to be caring and a good listener. Rather than sharing your knowledge initially, it is important to help establish a "partnership" with the patient by first asking the following question: "What is bothering you the most about your asthma?" Really listening to the patient and then addressing patient concerns is extremely important to successful education and long-term management.

Clinicians can be of invaluable assistance to the patient by repeatedly reinforcing education on the necessity of using anti-inflammatory therapies. Many patients underuse long-term preventive therapy because no health professional took the time to adequately instruct them that most asthma symptoms are preventable. Although underusing the most important medicines for long-term control, and recent literature and guidelines have emphasized the use of ICS/formoterol as the preferred reliever, many patients still overuse "quick relievers" (ie, SABAs). Health care providers must be able to detect these problems and intervene to enhance patient care.

Because a large percentage of patients have difficulty using inhaler devices, teaching patients the correct use of MDIs (alone or in combination with spacers) and dry powder inhalers is absolutely essential.[1,2] In one study, 89% of patients could not perform all of the steps for MDI use correctly.[105] Competent teaching requires observation of the patient using the devices initially and again on repeat visits to the clinic, hospital, or community pharmacy. Telling the patient about correct use is inadequate. Health professionals

must demonstrate the use of the devices (live or with videotapes) for patients who cannot use the devices correctly.

For videos that show proper use of many types of asthma inhalers and nebulizers, go to **https://www.nationaljewish.org/conditions/health-information/multimedia/devices-to-inhale-medication**.

Although there is more than one correct way to use an MDI, each manufacturer has gained FDA approval using one type of technique. Many asthma experts prefer to use a spacer or VHC to help ensure optimal efficacy. Spacers and VHCs are external devices that can be attached to the MDI, which may result in a larger amount of the aerosolized drug reaching the lungs instead, particularly in those who have difficulty coordinating the timing of actuation and inhalation. Proper MDI technique is difficult for many patients to master, and even those patients who display initial proficiency can experience a lapse in ability over time to correctly use an MDI. Much like a spacer, a VHC provides space in between the mouthpiece of the MDI and the mouth, but also incorporates a one-way valve that prevents exhalation into the device and may allow the patient to more easily and efficiently inhale the aerosolized drug particles. Upon actuation of the inhaler, the aerosol is suspended within the holding chamber, whereby the patient may take a single or, if needed, multiple inhalations from one actuation. Young children may particularly benefit from this device, which may also include a face mask. A VHC should be used in virtually all patients receiving ICSs via an MDI, even those with perfect MDI technique because a VHC enhances efficacy and reduces the risk of oropharyngeal candidiasis.[106–108] On the other hand, a VHC does not add efficacy to correct use of a β_2-agonist MDI. Although any VHC can be helpful, marketed devices that have a flow indicator whistle when inhalation is too fast are preferred (eg, AeroChamber®).

Some newer inhalers such as QVAR Redihaler® (beclomethasone) and ProAir RespiClick® (albuterol) are breath-actuated ones and do not need to be used with any type of VHC. In addition, there are now breath-activated "smart" inhalers (see Case 18-4) that measure inspiratory flow and patient adherence, and then upload this information to an application to be viewed by the patient and physician.

Studies have shown that health professionals, similar to some patients, generally are not competent in using MDIs.[106–108] Obviously, the clinician should practice with a placebo inhaler and gain competence before teaching a patient. Among clinicians who educate patients, pharmacists can be helpful in teaching correct use of MDIs. Unfortunately, many times, community pharmacists may not have the resources (ie, sufficient time and management support) and are not providing such teaching.

In addition to teaching the correct use of MDIs and spacers, clinicians should help patients via education regarding the correct use of breath-activated dry powder inhalers (eg, Twisthaler®, Diskus®, Flexhaler®, Ellipta®, RespiClick®) and nebulizing machines.[1,2] When using the Flexhaler®, for example, patients must clearly understand the need for a rapid (preferably 60 L/minute), deep inhalation (not slow as with an MDI). Adequate PIF rates may be difficult for some young children and elderly to generate.[109] In addition, patients need to breath-hold 10 seconds, if possible, as with an MDI.

Asthma Self-Management Plans

Objective monitoring of lung function at home with the use of peak flow meters can be very helpful to patients and health care professionals. EPR-3 discusses the debates about PEF versus symptom-based action plans.[2] Use of peak flow meters may be valuable in patients who have had severe exacerbations and those who are "poor perceivers" of deteriorating asthma control. Instructing patients on the correct use of the devices, including use of the green,

yellow, and red zones, is essential.[2] After establishing that optimal therapy has maintained the PEF in the "green zone" in the early morning, most patients can simply verify their values once daily in the early morning. Analogous to a traffic light, green, yellow, and red zones have been established to guide the patient and clinician. The green zone refers to a PEF that is 80% to 100% of "personal best" and generally indicates that therapy is providing good control. Before a course of optimal therapy to attain a personal best, the zones are set based on predicted values found in each peak flow meter package insert. The yellow zone indicates a PEF that is 50% to 79% of personal best. Patients should be instructed to call their physician or other health care provider for adjustment in preventive medication if the PEF stays in the yellow zone after using two puffs of a fast-acting β_2-agonist. The red zone indicates a PEF that is <50% of personal best. The patient should know to call his or her health care provider immediately if the use of an inhaled β_2-agonist does not bring the PEF to the yellow or green zone. **Figure 18-16** provides an example of PEF monitoring, and **Figure 18-17** gives an example of a written action plan.

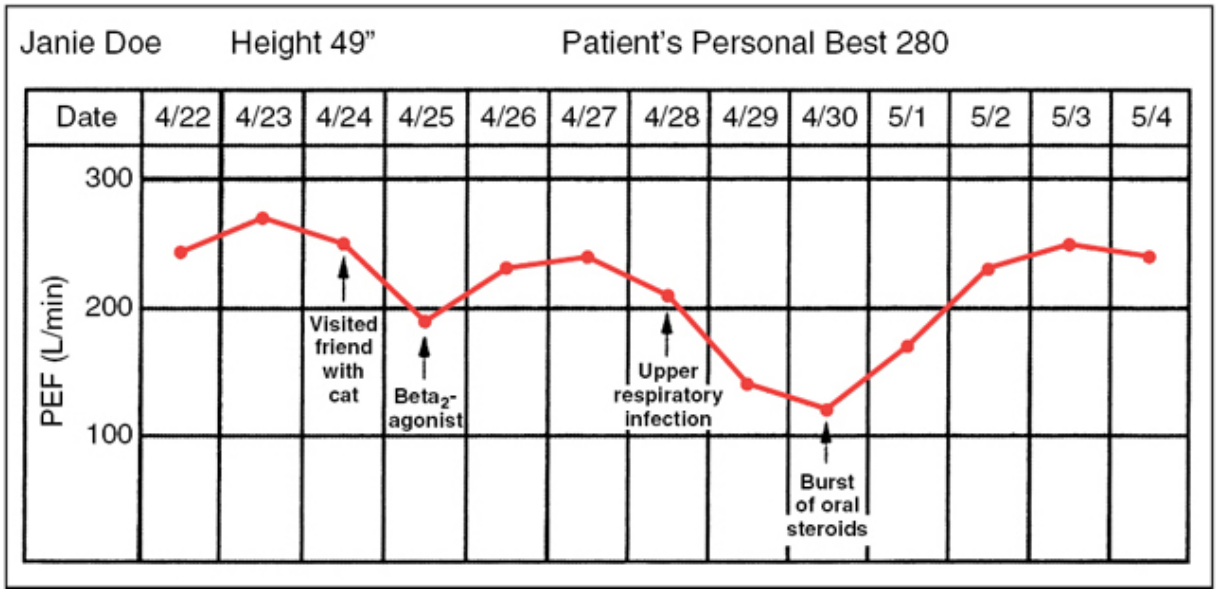

Figure 18-16 Asthma changes with time: patient monitoring and follow-up required. PEF, peak expiratory flow. (Adapted from National Institutes of Health. *Practical Guide for the Diagnosis and*

Management of Asthma. National Heart, Lung, and Blood Institute; 1997. NIH publication no. 97-4053.)

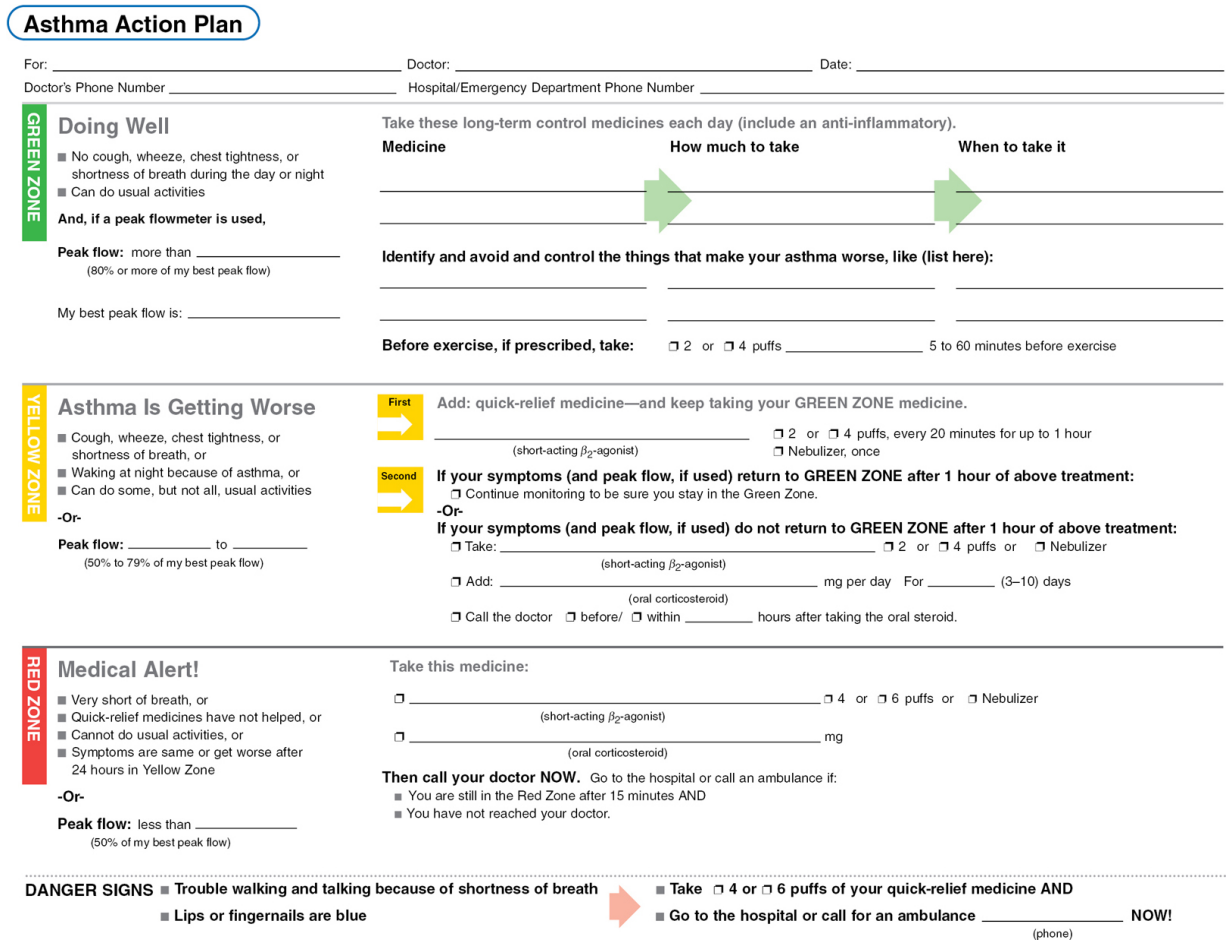

Figure 18-17 Sample asthma action plan. (Adapted from National Institutes of Health. *Expert Panel Report 3. Guidelines for the Diagnosis and Management of Asthma*. National Heart, Lung, and Blood Institute; 2007. NIH Publication no. 08-4051.)

Correct use of the peak flow meter includes standing, inhaling completely, forming a tight seal with the lips around the mouthpiece, exhaling as hard and fast as possible (blast!), and repeating this maneuver twice; the best of three attempts should be recorded. Beyond giving maximal effort when using peak flow meters, patients should be instructed to place the instrument well into the mouth on top of the tongue to avoid acceleration of air in the mouth with the

tongue and buccal musculature. In essence, “spitting” into the peak flow meter causes a dramatic false elevation in PEF.[110]

All patients need education regarding the benefits of long-term inhaled anti-inflammatory therapy. The clinician should explain with enthusiasm that controller medications are extremely effective and that it is the cornerstone of asthma management. The delayed onset and safety of ICSs must be stressed as well as the requirement of regular use every day. Showing the patient colored pictures, models, or a video of inflamed airways can be very helpful—these teaching aids are available from several pharmaceutical manufacturers. Finally, MDIs need special care, and every patient requires education on cleaning the actuator.

OUTCOMES

CASE 18-9, QUESTION 2: R.R. returns to the clinic 4 weeks later, and says he feels fantastic. How do you reinforce his success to increase the likelihood of long-term improvement?

Numerous studies have documented that applying the principles of the evidence-based guidelines[1,2] results in improved clinical outcomes, and many of these studies have been summarized in GINA.[2] Several studies have documented that pharmacists who are highly knowledgeable about asthma guidelines and who work closely with patients and physicians improve outcomes, including reduced ED visits and hospitalizations.[111] These successful studies involved highly motivated pharmacists, who were asthma experts based in university-affiliated clinics or in large private health maintenance organizations.

A randomized controlled trial based in community pharmacies in Canada with specially trained pharmacists has also shown very positive outcomes for patients with asthma.[112] When assessing the effect of comprehensive management on clinical outcomes, quality-of-life measures should be assessed (a validated questionnaire [the

Asthma Control Test] is shown in EPR-3[2]) as well as reduction in ED visits and hospitalizations.[1,2] To achieve optimal outcomes, attention to each of the four major components of management is required (objective assessment, environmental control, pharmacologic therapy, and patient education as a partnership). Examples of areas that pose special challenges for inner-city patients include psychosocial factors, exposure to cockroaches and rodents, underuse of controller medications, and passive cigarette smoke.[113] As part of overall management to improve outcomes, studies have emphasized again the importance of good inhalation technique with ICSs and education in the use of peak flow meters.

Targeted educational and intervention efforts in older (older than 60 years)[114] and in preschool-age[115] patients have been proved that these types of protocols can decrease ED visits and increase the quality of life.

Emphasizing the need for annual influenza vaccination in October is important. In addition, patients with asthma age older than 19 years should receive pneumococcal vaccine, and patients age 65 years and older should receive pneumococcal conjugate vaccine (see Chapter 64, Vaccinations for more details). Reinforcement of the importance of continued preventive therapy that has given such remarkable success is appropriate for R.R. and reassuring him that he is well in control of his asthma. The clinician should continue to work with him to further tailor the therapy, including control of rhinitis, to maintain optimal outcomes at the lowest dosages and on the simplest possible regimen. Research has further emphasized the goal of simplified regimens and achieving the lowest effective doses of anti-inflammatory therapy.

NONDRUG OPTIONS

CASE 18-9, QUESTION 3: R.R. is in the clinic a few months later. He is continuing to have excellent control of his asthma and allergic rhinitis. What is

your opinion on alternative nondrug options to lessen his reliance on prescriptions?

Complementary and alternative approaches have been used in the treatment of asthma, with one study finding teas and herbs as the most commonly used alternatives to prescription medicines. As with any herbal product, although some may work to a degree, such as ma huang, which contains ephedra (a bronchodilator), they are unregulated, and not well studied in terms of drug interactions and toxicity.[116] Also, as Roy et al discovered, it is not uncommon for a patient who takes herbals to decrease their intake of their prescribed effective medication, in this case, ICSs.[117]

Although not a “complementary alternative” therapy, bronchial thermoplasty, which aims to reduce smooth muscle tissue, thereby decreasing the amount of muscle available for bronchoconstriction, has been demonstrated to be efficacious in the management of severe, refractory asthma in selected cases.[118] However, the 2020 NIH guidelines recommend against its routine use outside of clinical trials because of both short-term risk and unknown long-term adverse events. However, in an individual case, it may be used where the benefits are deemed to outweigh the risks (a conditional recommendation against its use).[15]

Although it is unlikely that one single change (such as using a high-efficiency particulate air [HEPA] vacuum) to reduce a specific allergen exposure in the household will have a significant impact in lessening symptoms, multiple changes, such as pest control plus mold removal plus using a dust mite pesticide, for example, may be beneficial. For a complete list of mitigation strategies, the reader is referred to the 2020 Focused Updates to the Asthma Management Guidelines.[16] Sublingual immunotherapy (SLIT) is relatively new and is still being trialed in the United States, and was also not generally recommended for allergic asthma in the 2020 NIH guidelines (a “conditional” recommendation against its use).[16] However, specifically in the form of sublingual tablets, SLIT could be used in patients on a case-by-case basis, particularly in patients, for example, with asthma and concomitant allergic rhinoconjunctivitis

after shared decision between clinician and patient weighing the risks and benefits.[16] In contrast, subcutaneous immunotherapy (SCIT) has a long track record and is recognized as potentially beneficial by improving quality of life in patients with asthma with a concomitant allergy to which the patient is sensitive and regularly exposed.[16]

ACKNOWLEDGMENT

The authors gratefully acknowledge Timothy H. Self for his expert guidance and contributions for many previous editions.

Chronic Obstructive Pulmonary Disease

Timothy R. Hudd and Kathy Zaiken

CORE PRINCIPLES

1 Chronic obstructive pulmonary disease (COPD) is characterized by chronic airflow limitation and a range of pathologic changes in the lung, some significant extrapulmonary effects, and important comorbidities that may contribute to the severity of the disease in individual patients. Cigarette smoking is the major risk factor for COPD, and most cases of COPD are attributed to a current or past history of cigarette smoking. Exposure to indoor and outdoor air pollution, occupational dusts and fumes, and abnormal lung growth

CHAPTER CASES

Case 19-1 (Question 1)

	and development are other significant risk factors.	
2	Inhalation of noxious particles or gases, such as cigarette smoke, leads to the activation of resident immune and parenchymal cells, which, in turn, recruit additional inflammatory cells from the systemic compartment into the lung. The exact mechanisms responsible for the pathogenesis of COPD are not entirely clear, but likely involve activation of the innate and adaptive immune system, leading to chronic inflammation.	**Case 19-2 (Question 2)**
3	As COPD progresses, additional systemic consequences can arise, including cachexia, cardiac and skeletal muscle dysfunction, osteoporosis, depression, and anemia. Pulmonary rehabilitation is recommended to address these systemic manifestations.	**Case 19-2 (Question 5)**
4	The diagnosis of COPD is based on the presence of risk factors, clinical symptoms, and airflow obstruction determined by spirometric testing. Generally, COPD manifests in the fourth or fifth decade of life with symptoms of cough, wheeze, or dyspnea on exertion. The severity of disease is based on a grading system, which then guides therapy.	**Case 19-1 (Questions 1, 2)**
5	The only interventions that have been	**Case 19-1 (Question**

	consistent shown to reduce mortality in COPD are smoking cessation, oxygen therapy for patients with severe hypoxemia at rest, and lung volume reduction surgery for very select patients with advanced emphysema. 	the presence of the following symptoms: increased dyspnea, sputum volume, and sputum purulence.	
9	Individual patient factors should be considered before prescribing long-term oxygen supplementation in patients with stable COPD who experience mild-to-moderate desaturation while at rest or during exercise. However, long-term oxygen administration (>15 hours/day) has been shown to improve survival in patients with severe resting hypoxemia (PaO_2 ≤7.3 kPa [55 mm Hg] or SaO_2 ≤88%), when confirmed twice over a 3-week period. Supplemental oxygen should be titrated to a target saturation of ≥90% for maintenance in stable COPD.	**Case 19-4 (Question 1)**
10	Lung volume reduction surgery, which involves the surgical removal of parts of the lung to improve hyperinflation, can significantly improve quality of life, exercise tolerance, and mortality in patients with severe upper lobe emphysema and low exercise capacity despite pulmonary rehabilitation.	**Case 19-4 (Question 2)**

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a common preventable and treatable airway disorder characterized by

persistent respiratory symptoms and airflow limitation due to airway and/or alveolar abnormalities.[1] Dyspnea is the hallmark symptom of COPD, which may be accompanied by other common symptoms such as cough and sputum production. Airflow limitation is generally not fully reversible and attributed to an enhanced chronic inflammatory response in the airways following significant exposure to cigarette smoke, biomass fuels, and other noxious particles or gases.[1,2] Host factors including abnormal lung development, genetic abnormalities, and advanced age may predispose individuals to developing COPD.[1]

Emphysema (lung parenchymal destruction) and *chronic bronchitis* (chronic cough and phlegm production) are two commonly used terms that reflect disease spectrum and are often used as pathologic subtypes or *phenotypes* of COPD. More recent definitions have transitioned away from these terms, as pathologic features from both likely contribute to airflow limitation in patients with COPD.[1]

In 2001, the National Institutes of Health (NIH) and the World Health Organization (WHO) collaborated to develop the Global Initiative for Chronic Obstructive Lung Disease (GOLD) Report.[1] This document is updated annually and offers evidence-based strategies for the diagnosis, assessment, and management of COPD. In addition, other international expert groups have developed consensus guidelines aimed toward the prevention and management of acute exacerbations associated with COPD.[3,4]

Asthma is a separate and distinct obstructive airway disorder with features similar to COPD. However, airflow limitation and symptoms such as wheezing, cough, dyspnea, and chest tightness are usually episodic and reversible. Some patients may present with clinical features from both conditions, with 15% to 32% of patients sharing a dual diagnosis of asthma and COPD.[5] The term *asthma–COPD overlap* (ACO) is a common descriptor used in clinical practice to collectively describe patients who have persistent airflow limitation along with clinical features of both asthma and COPD.[5] Patients with ACO experience more frequent exacerbations, accelerated loss of lung function, higher health care resource utilization, and greater mortality compared to patients with asthma or COPD alone.[5]

Epidemiology

COPD affects an estimated 15.7 million Americans and is the fourth leading cause of death worldwide.[1,6] However, the true prevalence of COPD is believed to be much higher with an estimated 12 million more cases undiagnosed because of the insidious onset of the disease.[7] In 2010, total U.S. health care–related expenditures were an estimated 50 billion dollars, including $32 billion in direct costs.[8] COPD exacerbations are the most significant contributor to the cost burden of the disease, accounting for ~50% to 75% of all costs.[2]

COPD is also a leading cause of disability in the United States.[6] Surveillance data from the 2013 Behavioral Risk Factor Surveillance System found that patients with COPD were more likely to be unable to work (24.3% vs 5.3%), have difficulty walking or climbing stairs (38.4% vs 11.3%), and report limitations with daily activity because of health problems (49.6% vs 16.9%) compared with adults without COPD.[6]

The prevalence of COPD and associated costs are expected to continue to rise over the next few decades, at least, in part, because of the increased life expectancy of the general population and advanced age of patients who began smoking earlier in life.[1,8] Historically, the prevalence of COPD and related mortality was reported to be greater in males than that in females.[1] However, the prevalence of COPD among females has risen steadily in recent years and may now be higher than male.[6,7] The reason for this increase is likely multifactorial and may be due to changes in smoking patterns among females over the past century, and a growing body of evidence suggests females may be more vulnerable to the adverse effects of smoking.[9]

Risk Factors

Cigarette smoking is the major risk factor for COPD, and most cases are attributed to a current or past history of smoking.[1] In susceptible individuals, smoking elicits an abnormal inflammatory response that

damages the airways and lung parenchymal tissue, which accelerates decline in lung function.[10] It should be noted that fewer than half of smokers develop clinically significant COPD, suggesting a more complex interplay between host-related factors (ie, genetics, sex, age, etc.) and other environmental exposures.[11,12] Genome-wide association studies have successfully identified multiple loci associated with lung function and COPD, but precise genetic characteristics have not yet been elucidated.[1,13] One exception is α_1-antitrypsin deficiency (AATD), which affects ~1% to 2% of patients with emphysema.[12] Affected individuals have an inherited deficiency of this protective antiprotease and are at much higher risk for developing emphysema than the general population.[14]

Abnormal lung growth and development during gestation and throughout adolescence may predispose patients to COPD later in life, particularly in chronic smokers and in those who begin smoking at an early age.[15] In developing countries, poor indoor air quality has been associated with obstructive airway diseases, including COPD.[1] Approximately 3 billion people worldwide burn biomass fuels for heating and cooking, which significantly contributes to poor indoor air quality.[16] Occupational exposures to dusts and chemicals,[11,17] childhood respiratory illnesses, and certain infections, including tuberculosis and human immunodeficiency virus, may also lead to COPD.[1] Advanced age and low socioeconomic status are other known risk factors.[1]

Pathogenesis

The exact mechanisms responsible for the pathogenesis of COPD are not entirely clear, but likely involve activation of the innate and adaptive immune system, leading to chronic inflammation. In general, inhalation of noxious agents, such as cigarette smoke, leads to the activation of resident immune and parenchymal cells, which, in turn, recruit additional inflammatory cells from the systemic compartment into the resident tissue and airway.

The activation and recruitment of immune cells is largely mediated through the production and release of cytokines and chemokines. Recent evidence also supports a role for oxidant stress as a disease mediator.[18,19] The consequences of an oxidant-rich environment include the activation of inflammatory genes, inactivation of antiproteases, stimulation of mucus secretion, and increases in plasma exudate.

The most well-studied cause of COPD, and particularly emphysema, relates to protease–antiprotease imbalance. In this setting, inflammation promotes the production and release of proteases from inflammatory and parenchymal cells. When the local concentration of antiproteases becomes overwhelmed, proteases go unchecked and destroy the major connective tissue components in the lung, such as elastin, leading to the irreversible loss of alveoli. The classic example of this occurs in patients with AATD.

Although the traditional idea of disease pathogenesis focuses on smoking-related lung *injury*, more recent hypotheses suggest that another important component of disease pathogenesis may involve inadequate lung *repair.* Indeed, there is evidence that normal lung homeostatic mechanisms are altered in COPD. This may involve inadequate production of growth factors as well as altered regulation of apoptosis, or programmed cell death.[20]

Pathophysiology

The airflow obstruction caused by COPD is usually progressive and is attributed to pathologic changes in the lung that affect the proximal airways, peripheral airways, lung parenchyma, and pulmonary vasculature.[21] Alterations in tissue structure are caused by chronic inflammation that involves recruitment of inflammatory cells into the lung, as well as structural changes that result from repeated injury and tissue remodeling. The magnitude of structural changes and tissue dysfunction varies among patients and is often distinguished by two major phenotypes that include chronic bronchitis and emphysema. Chronic airflow limitation can result from both of these

processes. Recent guidelines[1,22] do not distinguish between these two entities; however, the classic definitions and pathophysiologic features are described here to aid in a better understanding of the disease process.

In the simplest view, *bronchitis* is inflammation of the bronchioles. The clinical definition from the American Thoracic Society (ATS) for *chronic bronchitis* is "the presence of chronic productive cough for 3 months in each of two consecutive years in a patient in whom other causes of chronic cough (eg, asthma, congestive heart failure, gastroesophageal reflux) have been excluded."[23] *Emphysema* is described as "abnormal permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis." The degree of impairment of the small airways (bronchioles) or the lung parenchyma (alveoli and supporting structures) directly influences tissue dysfunction and the clinical symptoms of the patient.

LARGE (CENTRAL) AND SMALL (PERIPHERAL) AIRWAYS

The large airways, which include the trachea and first generations of the bronchi, are a major site of inflammation and mucus hypersecretion. This results from an increase in numbers (hyperplasia) and enlargement (hypertrophy) of the submucosal glands and mucus-producing goblet cells within the surface epithelium.[24,25] Overproduction of mucus in the large airways results in a chronic productive cough, as observed in chronic bronchitis, but this alone does not have a major impact on airflow limitation. Mucus hypersecretion, coupled with impaired ciliary function, reduces mucociliary clearance, increases the accumulation of secretions, and enhances the risk of bacterial colonization in an otherwise sterile environment.[26] As a result, recurrent infections often occur owing to the inability to clear pathogens.

The peripheral airway is composed of the smaller bronchi down to the terminal bronchioles, the smallest branches in the lung that are not involved in gas exchange. The extent of inflammation, fibrosis, and airway exudate in the peripheral airway correlates best with the

reduction in airflow as measured by a decrease in forced expiratory volume in the first second of expiration (FEV_1) or the FEV_1 to forced vital capacity (FVC) ratio.[27] After age 35, nonsmokers experience a decline in FEV_1 of about 20 to 30 mL/year. In smokers, an accelerated decline of 50 to 120 mL/year may be observed.[28] A model of the annual decline in lung function in nonsmokers, smokers, and susceptible smokers is illustrated in **Figure 19-1**. Chronic obstruction of the peripheral airway also results in air trapping on expiration, which contributes to hyperinflation. Hyperinflation places the respiratory muscles at a mechanical disadvantage and further reduces respiratory capacity. Hyperinflation can become more pronounced during exercise, leading to dyspnea and decreased exercise capacity. It is now known that hyperinflation can occur early in the course of COPD and is an important cause of exertional dyspnea.[29]

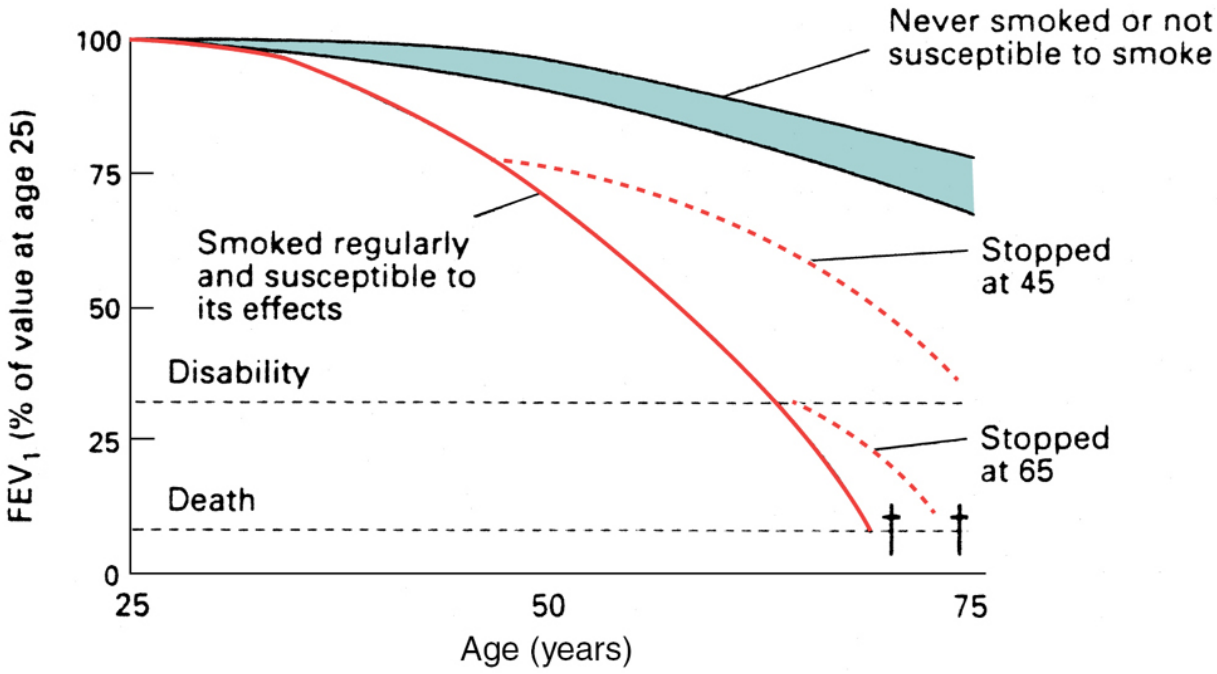

Figure 19-1 Model of annual decline in FEV_1 with accelerated decline in susceptible smokers. On stopping smoking, subsequent loss is similar to that in healthy nonsmokers. PARENCHYMAL DESTRUCTION

The terminal bronchioles lead directly to the alveolar ducts and sacs, the major site where gas exchange occurs. Emphysema is characterized by the destructive loss of alveolar walls and enlargement of the terminal airspaces, resulting in a loss of gas-exchanging surface area.[26] In advanced cases, large, balloon-shaped bullous lesions may develop. Rupture of these bullae (pneumothorax) can lead to collapse of lung segments (pneumothorax).

SIGNIFICANT COMORBID ILLNESS

In the later stages of disease, chronic hypoxemia causes persistent vasoconstriction in the lung vascular bed, particularly the small pulmonary arteries. This can result in permanent structural alteration of the blood vessels, causing intimal hyperplasia and smooth muscle hypertrophy.[30] The loss of pulmonary capillaries in emphysema can also contribute to increased pulmonary vascular pressures. The cumulative impact of vascular changes can result in progressive pulmonary hypertension and, eventually, right-sided cardiac failure (cor pulmonale).

As COPD progresses, additional systemic consequences can arise, including cachexia, skeletal muscle dysfunction, osteoporosis, depression, and anemia. The cause of these additional systemic disease processes is not entirely clear, but likely involves the dynamic interplay of progressive respiratory dysfunction, lung and systemic inflammation, side effects from medication use, and physical debilitation. In summary, although COPD is primarily a disease of the large and small airways and adjacent alveolar structures, it also includes important systemic consequences. The clinical consequences of the morphologic and pathophysiologic alterations include progressive dyspnea on exertion, chronic cough

and sputum production, increased risk for respiratory infections, deconditioning, and an overall reduction in quality of life.

COMPARISON WITH ASTHMA

COPD and asthma are common obstructive airway disorders, and both illnesses can coexist in the same patient. Nevertheless, these conditions should be considered as separate and distinct entities (**Table 19-1**). For example, although inflammation is a key component of both conditions, the pattern of inflammation differs significantly (**Table 19-2**). As a result, the pathophysiologic consequences, patient symptoms, and response to medications typically differ. Asthma is generally not progressive, and symptoms and airflow obstruction are often completely reversible. Patients with asthma respond well to anti-inflammatory medication, including inhaled corticosteroids (ICSS). Furthermore, in the absence of an acute exacerbation, significant gas exchange abnormalities are uncommon. COPD, on the other hand, is a progressive and often fatal disorder. Although bronchodilators are helpful in COPD, the degree of bronchodilator reversibility is typically less than that seen in asthma. In addition, the beneficial effects of anti-inflammatory medication, including ICS, are much more modest. Patients with COPD, particularly those with emphysema, have substantial derangements in pulmonary gas exchange, even at baseline.

Table 19-1
Clinical Features of Asthma, COPD, and Asthma–COPD Overlap (ACO)

Clinical Feature	COPD	Asthma	Asthma–COPD Overlap
Age of onset	>40 years of age	Childhood, but can occur at any age	Usually ≥40 years of age, but may have had symptoms in childhood or adolescence
Possible symptoms	Dyspnea, chronic cough, sputum production	Dyspnea, cough, wheeze, chest tightness	Mixed symptoms
Symptom pattern	Persistent and slowly progressive Present daily, worse with exertion or exercise	Vary day to day and may be episodic based on trigger exposure Often worse at night or early morning	Persistent and worse with exertion though variability may exist
Risk factors	History of chronic exposure to cigarette smoke, biomass fuels, or noxious particles and gases α_1-Antitrypsin deficiency (<2% of cases)	Atopic conditions (ie, allergies, eczema, etc.) Family history of asthma	History of asthma with chronic exposure to cigarette smoke, biomass fuels, or noxious particles and gases
Postbronchodilator FEV_1 reversibility[a] FEV_1/FVC ratio	Usually little to no change FEV_1/FVC <70%	Reversible and may be normal between symptoms	Airflow limitation is usually not fully reversible and often varies over time
Chest x-ray	Hyperinflation	Usually normal	Hyperinflation

FEV_1, forced expiratory volume in the first second of expiration; FVC, forced vital capacity.

[a]Reversibility is defined as an increase in FEV_1 of >200 mL and 12% from baseline measure after inhalation of a short-acting β_2-agonist.

α_1-ANTITRYPSIN DEFICIENCY

The best characterized antiprotease in the lung is α_1-antitrypsin. This serum glycoprotein is primarily produced in the liver and works by binding to and neutralizing proteases. As described previously, cigarette smoke can activate and attract inflammatory cells into the lung, thereby promoting the release of proteases, such as neutrophil elastase. Cigarette smoke can also inactivate endogenous protease inhibitors, including α_1-antitrypsin, further supporting protease activity and increasing the risk of tissue damage. This risk of tissue damage is greatly accentuated in patients with AATD.

AATD is a genetic disorder responsible for 1% to 2% of patients with COPD.[12] It is more common in patients of European ancestry and has been associated with other conditions, including liver disease.[12,31] The diagnosis of AATD is made by measuring circulating serum α_1-antitrypsin levels, followed by phenotype analysis.[31,32] The *SERPINA1* gene (also known as PI) is responsible for producing α_1-antitrypsin, and mutations in this gene can affect production. More than 120 mutations in the *SERPINA1* gene have been identified, but not all lead to AATD.[33] Inherited alleles are assigned letters to represent the migration of the molecule in an isoelectric pH gradient.[14]

The PiM allele confers production of the fully functional protein. Accordingly, a homozygous PiMM individual will produce a functional protein with normal plasma concentrations. Other gene types include, but are not limited to, PiS (normal serum levels of a poorly functioning enzyme), PiZ (an active form but poorly secreted, leading to low circulating levels), and Pi null (gene polymorphism leads to production of a truncated protein and undetectable serum levels of functional protein). Different allele pairs can exist. PiMZ and PiSZ are heterozygous disorders, and PiSS is a homozygous phenotype, all with >35% of normal enzyme activity and a relatively low risk of developing emphysema. PiZZ is a rare homozygous disorder characterized by accelerated lung destruction and serum α_1-antitrypsin levels of ~15% of normal. In these rare patients, the disease develops as early as age 20, but more typically, it occurs in the fourth to fifth decades of life.[14]

Replacement therapy is available for patients with COPD with documented AATD and emphysema. Patients who do qualify typically receive weekly intravenous infusions of α_1-antitrypsin to maintain acceptable antiprotease activity and minimize the progression of lung disease. This therapy is very expensive, and it is not well tolerated by some (fever, chills, allergic reactions, flulike symptoms). Replacement therapy may improve outcomes in patients with AATD, documented emphysema, and an FEV_1 between 30% and

65% of predicted.[32] Several formulations of α_1-antitrypsin are available: Aralast®, Prolastin®, Zemaira®, and Glassia®. No clinically significant differences exist among these preparations. Because the α_1-antitrypsin products are derived from pooled human plasma, there are also associated risks for the transmission of infectious diseases (eg, viral infections and Creutzfeldt–Jakob disease). Overall, the use of the α_1-antitrypsin replacement therapy remains controversial, and some have argued that this therapy cannot be recommended based on a lack of proven clinical benefit and high cost of treatment.[34]

DIAGNOSIS AND PATIENT ASSESSMENT

The diagnosis of COPD is based on the presence of risk factors (generally smoking), clinical symptoms, and airflow obstruction on spirometric testing.[1] Generally, individuals with COPD present in the fourth or fifth decade of life with symptoms of cough, wheeze, or dyspnea on exertion.[35] Patients usually have at least a 10-pack-year history (eg, averaging one pack of cigarettes a day for 10 years) of cigarette smoking. Because the severity of COPD is related to the cumulative exposure to cigarette smoke, patients with more severe disease are likely to be older with a heavier smoking history. Cough and sputum production may be present for many years before airflow limitation develops, but not everyone with those symptoms will develop COPD. Dyspnea is a hallmark symptom and a major cause of disability and anxiety.[1]

On physical examination, patients with early COPD may not exhibit any overt clinical signs or symptoms.[1] In more advanced stages, objective findings may include the presence of a barrel chest (defined as an increase in the anteroposterior diameter of the chest), rales (defined as intermittent, nonmusical, brief crackle sounds), rhonchi (defined as continuous, musical high- or low-pitched sounds), prolonged expiratory phase, and cyanosis.[24] Symptomatic patients may present with decreased breath sounds, wheezes, or

slight rales on auscultation. In advanced disease, cyanosis, edema, intercostal retractions, and pursed-lip breathing may be present.[24]

Spirometry Testing

Spirometry is the gold-standard measurement in assessing and monitoring obstructive lung disease and is required for a diagnosis of COPD.[1,22] In the evaluation of COPD, spirometry testing should be performed according to published guidelines, when the patient's condition is stable and after administration of a short-acting bronchodilator, such as two to four puffs (90 µg/puff) of albuterol by metered-dose inhaler (MDI).[1,5] During spirometry, a full breath is taken, followed by a forceful exhalation of all the air that can be exhaled (FVC). Flow rates and volumes of air that are expired at different time intervals can be recorded (**Fig. 19-2**). The FEV_1 is the volume of air that can be expired within the first second of an FVC maneuver. A decrease in the FEV_1/FVC ratio indicates airflow obstruction. Although the range of normal for FEV_1/FVC depends on the age, sex, and height of the patient, a value of <0.70 indicates airflow obstruction that is compatible with COPD.[1,22] Also, patients with COPD may have some improvement in spirometry testing with an acute bronchodilator challenge. The degree of reversibility is typically less than that seen with asthma, although up to 50% of patients with moderate-to-severe emphysema will have an increase in FEV_1 with acute bronchodilator challenge that meets ATS criteria as significant. In addition to being critical for making the diagnosis of COPD, spirometry also affords the best objective way to monitor disease progression and should be considered if there has been a persistent change in clinical symptoms (eg, worsened dyspnea). Four "grades" are used to classify the degree of airflow limitation using postbronchodilator spirometric results in patients with an FEV_1/FVC <70%:

- GOLD 1 (mild): FEV_1 ≥80% predicted

- GOLD 2 (moderate): FEV_1 ≥50% to 80% predicted
- GOLD 3 (severe): FEV_1 ≥30% to 50% predicted
- GOLD 4 (very severe): FEV_1 <30% predicted[1]

All rights reserved. Available from https://www.goldcopd.org.)

Deteriorating lung function is associated with increased prevalence of hospitalizations, exacerbations, and associated mortality at the population level.[1] However, FEV_1 is an unreliable clinical indicator when used alone to predict exacerbation or mortality risk at the individual patient level.[1] Although optimal frequency of spirometric testing for patients with COPD is not known, some groups recommend annual monitoring to identify patients whose lung function may be declining rapidly.[1]

Other pulmonary function testing is sometimes used to assess patients with COPD. The determination of lung volumes, including the total lung capacity (TLC) and residual volume (RV), as well as measurements of the diffusing capacity for carbon monoxide (DLCO) may provide more detail regarding lung physiology. For example, a reduction in DLCO indicates disruption or destruction of the alveolar capillary interface and correlates with the degree of emphysema. Determination of lung volumes may be used to assess the presence of concomitant restrictive lung disease (eg, idiopathic pulmonary fibrosis) in the case of diagnostic uncertainty. Patients with COPD typically have normal or increased lung volumes; a reduction in TLC may indicate a superimposed restrictive process. Furthermore, lung volumes and diffusion capacity are used to assess patients for surgical procedures, such as lung volume reduction surgery.[1,36] In most cases, however, spirometric testing is adequate to make the diagnosis of COPD and follow the course of disease.[1,22]

A chest x-ray (CXR) may be performed during the initial assessment of patients with COPD. Because the CXR lacks sensitivity

and demonstrates minimal changes until COPD is moderately severe, its main utility is in ruling out other disease processes, possibly contributing to the patient's symptoms. In severe disease, the chest radiograph may indicate hyperinflation, manifested by a flattened diaphragm, or evidence of pulmonary arterial hypertension, characterized by enlarged pulmonary arteries.

Assessing the oxygen status of a patient with COPD can be done by pulse oximetry. This should be considered in patients with dyspnea and advanced disease and patients with evidence of right ventricular pressure overload (eg, peripheral edema or jugular venous distension). Although a decrease in pulse oximetry (normal, ≥97%) is common in COPD, values of 88% or less are consistent with chronic respiratory failure and qualify the patient for supplemental oxygen. Arterial blood gas (ABG) determination is generally reserved for patients with severe disease (ie, an FEV_1 <50% of predicted). ABGs can more precisely define the oxygen status of a patient and can be used to assess whether the patient has carbon dioxide retention (normal P_{CO_2} = 35–45 mm Hg). Determining the α_1-antitrypsin concentration is indicated for patients developing COPD before age 45 and for patients who have emphysema without a significant history of cigarette smoking or who have a family history of emphysema.[1]

Classification of Severity and Clinical Presentation

Earlier guidelines categorize the severity of COPD based on the degree of airflow obstruction as assessed by the FEV_1.[23] However, lung function has been found to be a poor indicator of disease severity when used alone. Thus, the GOLD Report offers a systematic approach to better individualize patient assessment of symptom burden and exacerbation risk to guide initial therapy (**Fig. 19-3**).[1] Patients may be initially categorized into one of the following groups: group A: low risk, less symptoms; group B: low risk, more symptoms; group C: high risk, less symptoms; and group D: high risk, more

symptoms. Moreover, comorbidities, serum eosinophil counts, and other patient's related characteristics should be considered before initiating therapy.

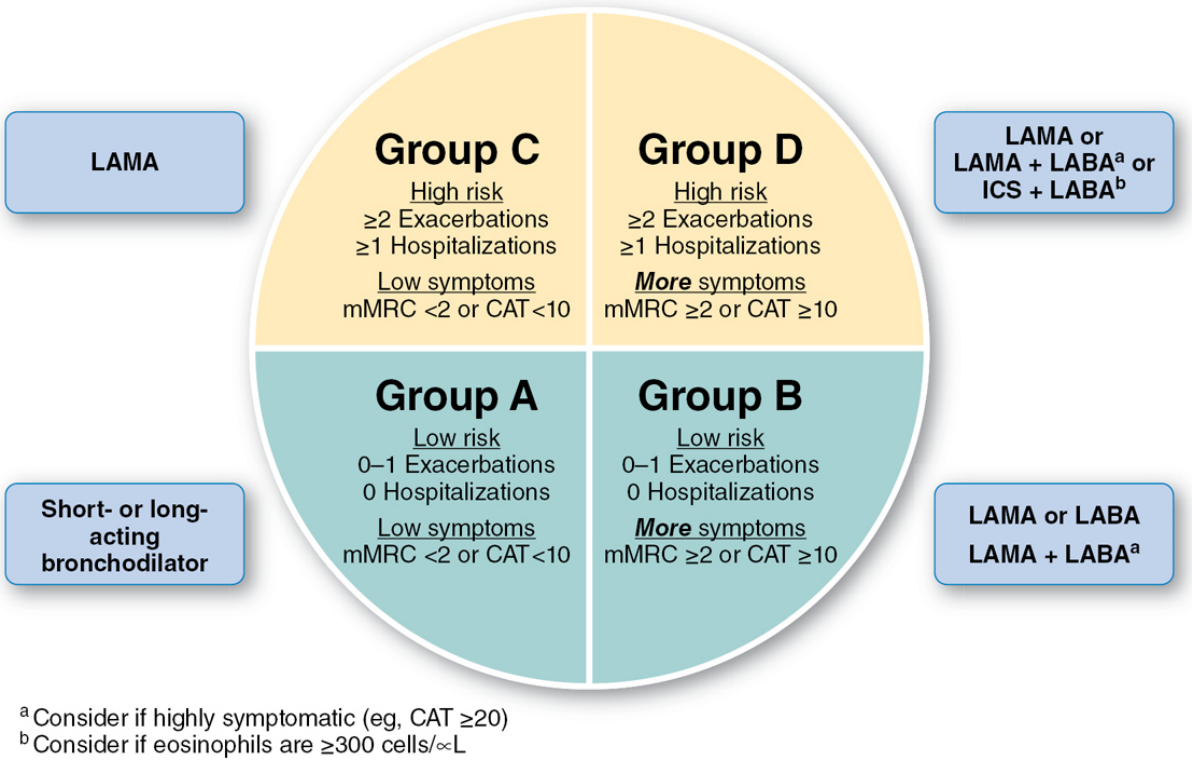

Figure 19-3 Initial pharmacologic selection by COPD group. CAT™, COPD Assessment Test; ICS, inhaled corticosteroid; LABA, long-acting β_2-agonist; LAMA, long-acting antimuscarinic (anticholinergic); mMRC, modified Medical Research Council Questionnaire. (From the Global Strategy for Diagnosis, Management, and Prevention of Chronic Obstructive Lung Disease 2020. Copyright © 2020 Global Initiative for Chronic Obstructive Lung Disease, Inc. All rights reserved. Available from https://www.goldcopd.org.)

Two steps should be followed when using the ABCD assessment tool. The first step is to assess patient symptoms. Several reliable questionnaires such as the Modified British Medical Research Council Questionnaire (mMRC), COPD Assessment Test (CAT), and COPD Control Questionnaire (CCQ) may be used to assess symptom burden and health status. The mMRC only assesses the

impact of breathlessness on health-related quality of life. However, patients with COPD often exhibit additional symptoms, such as cough, chest tightness, and mucus production. Therefore, scales that provide a more comprehensive assessment of symptoms (eg, CAT) may be preferred by some clinicians. Nevertheless, patients are considered to have a high level of symptoms when scoring ≥2 on the mMRC or ≥10 on the CAT. Of note, it is only necessary to use one of these scales when assessing symptom burden.

The second step involves an assessment of the patient's risk for future exacerbations. Patients are considered to be in the "high-risk" category if the patient has experienced two or more exacerbations in the previous year or if the patient has had one exacerbation that led to a hospitalization within this time period.[1]

Although the GOLD management strategy can provide important prognostic information, other comprehensive assessment tools may too provide discriminating information with regard to survival in COPD. For example, a scoring system based on body mass index, obstruction on spirometry, dyspnea level, and exercise capacity (BODE) can predict survival in COPD better than the FEV_1 alone.[37]

GENERAL MANAGEMENT CONSIDERATIONS

The natural course of COPD is highly variable, generally spanning 20 to 40 years and influenced by numerous factors, including genetic predisposition, exposure to inhaled irritants (tobacco smoke, workplace, and/or environmental pollutants), and repeated infections.[38] The overarching goals of COPD management involve two main principles. First, to reduce symptoms (ie, relieve symptoms, improve exercise tolerance, and improve health status); and second, to reduce risk (ie, prevent disease progression, prevent and treat exacerbations, and reduce mortality).[1] Unfortunately, the only interventions that have been proven to reduce mortality in COPD are smoking cessation, oxygen therapy for patients with severe

hypoxemia at rest, and lung volume reduction surgery for very select patients with advanced emphysema.[36,39–41] As such, many of the interventions are aimed at alleviating symptoms and maximizing quality of life.

Because continued cigarette smoking is associated with accelerated progression of disease in susceptible smokers, smoking cessation is critical to disease treatment. Strategies for smoking cessation are detailed in Chapter 91, Tobacco Use and Dependence. The benefits of smoking cessation in COPD include decreases in respiratory symptoms, exacerbation rate, and decline in lung function.[28,42] It should also be noted that cardiovascular complications, including coronary artery disease, are more common in patients with COPD and that smoking cessation may attenuate morbidity and mortality from this complication.

Immunizations provide protection against serious illness and death in patients with COPD.[43] The efficacy, benefit, and cost-effectiveness of vaccination against influenza among this population are significant.[44] In addition, the pneumococcal polysaccharide vaccine is recommended to all patients with COPD,[1] as well as in adult patients age 19 to 64 years who smoke cigarettes or have chronic lung disease.[45]

Pulmonary rehabilitation is an exercise-based program aimed at maximizing the patient's functional status and quality of life. Multiple studies have now documented the beneficial effects of pulmonary rehabilitation, particularly with respect to improved exercise tolerance and alleviation of dyspnea.[46] In addition, cost-effective analysis suggests that pulmonary rehabilitation programs are very cost-effective.[1,46] Pulmonary rehabilitation programs are multidisciplinary programs typically running for 6 to 12 weeks, two to three sessions per week. However, no consensus on the optimal duration of pulmonary rehabilitation currently exists.[46] A number of interventions are used, including breathing retraining, psychosocial counseling, education, dietary counseling, and airway clearance techniques for patients with chronic sputum production. Arm strengthening and arm endurance exercises are important because

patients with COPD commonly have excessive dyspnea when using their upper extremities.[46] The most important component of a pulmonary rehabilitation program is lower extremity endurance training, often using a treadmill or bicycle ergometer. Because the large muscle groups have diminished oxidative capacity,[47–49] likely related to deconditioning and chronic inflammation,[50,51] patients with COPD convert to anaerobic metabolism at low levels of exercise. This leads to increased lactate production for a given level of activity[52] and, subsequently, increased CO_2 production. Lower extremity endurance training can significantly improve mitochondrial oxidative capacity in patients with COPD.[53] This physiologic benefit is believed to be an important mechanism whereby pulmonary rehabilitation exerts its effect. Other important effects, such as alleviation of depression and anxiety, may be important as well.[46]

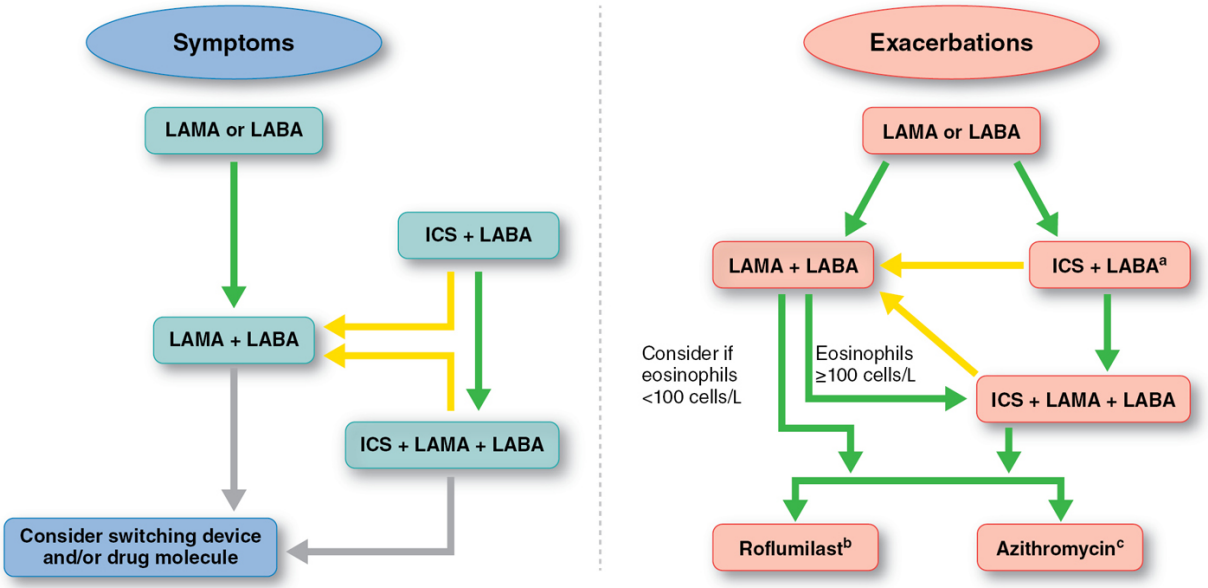
As mentioned, patients with severe resting hypoxemia have improved mortality with supplemental oxygen treatment. Long-term oxygen administration (>15 hours/day) has been shown to improve survival in patients with severe resting hypoxemia (Pa_{O_2} ≤7.3 kPa [55 mm Hg] or Sa_{O_2} ≤88%), when confirmed twice over a 3-week period.[1] Conversely, oxygen therapy does not increase the time to first hospitalization or death in patients with moderate oxygen desaturation while at rest (Sp_{O_2}, 89%–93%) or in those who experience exercise-induced desaturation.[54]

PHARMACOTHERAPY

The fundamental goals of medication use are to prevent or control symptoms, reduce the frequency and severity of exacerbations, and improve both health status and exercise tolerance.[1,22] None of the existing medications used to treat COPD have been conclusively shown to modify the long-term decline in lung function.[1] Therefore, therapy should be individualized and aimed toward symptom management and reducing future risk of exacerbations.[1] Treatment

goals should be realistic and developed jointly by the caregiver and the patient.

After medications are modified or prescribed, routine follow-up visits are recommended to evaluate treatment response. The process of "Review," "Assess," and "Adjust" may be employed as a guiding principle of pharmacologic management and offers a systematic approach to assessing response to therapy.[1] During the "Review," the emphasis is on identifying "treatable traits" in order to determine whether further treatment is necessary to manage "dyspnea" or prevent "exacerbations." Before modifying therapy, clinicians should "Assess" proper inhaler technique, medication adherence, and impact of nonpharmacologic interventions before adjusting therapy. If a change in therapy is necessary, escalation and de-escalation strategies are available to "Adjust" therapy, which may involve switching to an alternative inhaler device or drug product or both (**Fig. 19-4**).



[a] Consider ICS if serum eosinophils are ≥300 cells/L or if ≥100 cells/L AND 2+ exacerbations or 1 related hospitalization
[b] Consider if chronic bronchitis and FEV1 <50% predicted
[c] Consider in former smokers

Yellow arrows represent de-escalation of the ICS component if pneumonia, or if inappropriate original indication, or if lack of response to ICS

Figure 19-4 Follow-up pharmacologic escalation/de-escalation strategies group. *Green arrows* denote escalation strategies. *Yellow arrows* denote ICS removal, which should be considered if

pneumonia, lack of response, or if inappropriately prescribed initially. ICS, inhaled corticosteroid; LABA, long-acting β_2-agonist; LAMA, long-acting antimuscarinic (anticholinergic). (Adapted from Global Initiative for Chronic Obstructive Lung Disease [GOLD]. Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. Updated 2020. Accessed September 3, 2020. http://www.goldcopd.org.)

Although the standard for assessing benefit from treatment has been to measure spirometric improvement in FEV_1, many patients will not demonstrate noticeable changes after either an acute or extended therapeutic trial of any therapy. Increasingly, clinicians are considering other measures to determine the benefit of therapy, including measuring improvements in quality of life, dyspnea, and exercise tolerance.[55] Other appropriate measures may include COPD exacerbation rates and utilization of health care resources. In most patients, it is important to consider the use of multiple outcome measures, both objective and subjective, to guide the therapeutic decision-making process.

Bronchodilators

Bronchodilators are central to the symptomatic management of COPD and include short-acting β_2-agonist and long-acting β_2-agonist (LABA), short- and long-acting anticholinergic agents, and theophylline. These medications, although pharmacologically distinct, improve airflow, primarily by reducing bronchial airway smooth muscle tone. In COPD, the spirometric response, as measured by FEV_1, can be variable and, in many cases, will demonstrate no change, although the patient may subjectively feel better. This can be attributed to treatment facilitating emptying of the lungs and a reduction in thoracic hyperinflation at rest and during exercise. No clear evidence exists for benefit of one bronchodilator over another in the chronic management of COPD, although inhaled therapy is generally preferred to oral therapy to achieve a more rapid

onset of action and to minimize the risk of systemic exposure and adverse events. Generally, initial treatment selection is based on the frequency and severity of symptoms, as well as future exacerbation risk (Fig. 19-3). Additional factors such as product availability, cost, and patient preference may further allow treatment to be individualized.[1]

Short-acting β_2-agonists (eg, albuterol) with or without a short-acting anticholinergic (eg, ipratropium) is usually preferred for exacerbations and acute symptoms because of their more rapid onset of action and relatively short duration of activity when compared with long-acting agents.[1] A short- or long-acting bronchodilator should be offered to patients who have few symptoms and are at a low risk for exacerbations (group A).

Long-acting bronchodilators are preferred to short-acting agents for patients with a greater symptom burden, because the bronchodilator effect is sustained for a longer duration, thus reducing the number of daily inhalations. This strategy will also likely enhance patient adherence. For group B patients presenting with severe breathlessness, a combined bronchodilator therapy may be used as initial therapy.[1] The adverse effect profile of inhaled bronchodilators, particularly β_2-agonists, is dose dependent. The most common adverse effects are an extension of stimulation of β_2-adrenergic receptors that can produce resting sinus tachycardia or provoke cardiac dysrhythmias in predisposed individuals, especially the elderly. Precipitation of somatic tremors and hypokalemia can also occur with excessive use.

The relationship between β_2-agonist use and cardiovascular complications remains somewhat controversial. It is recognized that albuterol and long-acting inhaled β_2-sympathetic agents can induce systemic sympathetic states, hypokalemia, and other metabolic derangements that can contribute to cardiac rhythm disturbances. This has led to speculation that these abnormalities could contribute to an increase in cardiovascular death among patients with COPD using β_2-agonist inhalers.[56] Nevertheless, this speculation has been

largely refuted by the TORCH (Towards a Revolution in COPD Health) study, in which >6000 patients with COPD were randomly assigned to treatment with salmeterol, fluticasone, combined salmeterol–fluticasone, or placebo.[57] Overall mortality, cardiovascular mortality, and cardiovascular-related adverse events were no greater in the salmeterol group compared with any of the other groups.

Inhaled antimuscarinics inhibit bronchoconstriction primarily by inhibiting the effects of acetylcholine on M3 receptors expressed on airway smooth muscle.[58] These agents are generally well tolerated by virtue of their minimal systemic absorption. Excessive dry mouth is the most common adverse effect reported with inhaled anticholinergic agents, both short and long acting. It has been suggested that regular use of inhaled anticholinergic agents increases the risk of cardiovascular complications.[59,60] However, more recent large prospectively performed randomized trials have found a decreased risk of cardiovascular complications among patients with COPD using the long-acting anticholinergic tiotropium on a regular basis.[61,62]

It is not unusual to find reports in the literature that suggest superiority of one bronchodilator class versus another for COPD treatment[3,63] It is difficult, however, to predict individual responses to treatment. For some patients, β_2-agonist bronchodilators will increase airflow, improve pulmonary function test results, and reduce symptoms of dyspnea.[64] Others may achieve greater improvement with an anticholinergic in comparison with a β_2-agonist.[65,66] Still others may not have a reversible component with either drug, but may perceive symptomatic benefit.[67,68] Thus, the therapeutic regimen should be reviewed with the patient at each follow-up visit to assess response. Careful review of adherence, technique, and response to therapy should be assessed before adjusting therapy.

Theophylline is a methylxanthine that induces bronchodilation by relaxing the smooth muscle of the bronchi. Although not fully understood, its pharmacologic activity has been attributed to nonselective inhibition of phosphodiesterase (PDE), inhibition of extracellular adenosine (a bronchoconstrictor), stimulation of

endogenous catecholamines, and antagonism of prostaglandins PGE_2 and $PGF_{2\beta}$.[69] Theophylline has been shown to provide greater symptomatic improvement when compared with placebo, though it is considered to be less effective and usually less well tolerated than inhaled long-acting bronchodilators.[1] Theophylline may provide additional symptomatic improvement via stimulation of diaphragmatic contractility and anti-inflammatory effects. However, the clinical significance of these findings remains to be determined.[1,58]

Currently, theophylline is reserved for patients who do not tolerate, or fail to adequately respond to, a combination of first-line bronchodilators. It is relatively inexpensive and studies showing clinical benefit have involved mostly slow-release preparations. The major limitation of theophylline is its relatively narrow therapeutic index, potential to cause significant adverse events, and requirement for blood monitoring of drug levels.[1]

Selective Phosphodiesterase 4 Inhibitors

Roflumilast (Daliresp®) is an orally administered selective PDE4 enzyme inhibitor approved to reduce the risk of COPD exacerbations in patients with severe COPD associated with chronic bronchitis and a history of exacerbations.[70] Recent guidelines recommend the use of roflumilast in patients who are not adequately controlled by long-acting bronchodilators and continue to experience frequent exacerbations. It has been recommended to use this agent in combination with at least one long-acting bronchodilator.[1] Although roflumilast has been shown to improve FEV_1 by 40 to 60 mL compared to placebo, it is not a bronchodilator and is not indicated to relieve acute bronchospasm.[70,71] In comparison with theophylline, roflumilast has much less potential for drug–drug interactions and does not require drug-level monitoring. Though it is metabolized to an active metabolite via CYP3A4 and CYP1A2 pathways, it should be used with caution in patients receiving strong inducers or inhibitors of these enzymes and should be avoided in those with significant hepatic impairment. Significant adverse effects, including diarrhea,

nausea, weight loss (~2 kg), and adverse psychiatric effects, such as anxiety and depression, have been reported.[1,70,71] A starting dose of 250 µg once a day for 4 weeks may reduce the rate of treatment discontinuation in some patients. However, roflumilast 250 µg daily is not an effective therapeutic dose.[70]

Corticosteroids

Historically, initiation of a short (2-week) course of oral corticosteroids was often advocated to identify patients with COPD who might benefit from long-term treatment. Recent evidence, however, indicates that a short course challenge is a poor method to predict patients who will benefit from long-term ICS use.[72,73] Given the lack of evidence and risk for significant side effects that include steroid myopathy and loss of bone density, chronic systemic corticosteroid therapy is not generally recommended. For patients with COPD experiencing an acute exacerbation of their disease, the short-term use of systemic corticosteroids has proven efficacy.[74]

In contrast, inhalation of corticosteroids leads to substantially less systemic absorption, thereby minimizing many of the risks associated with systemic corticosteroid therapy. On this basis, studies have been conducted to evaluate the potential benefit of ICS maintenance therapy.[75] Well-conducted clinical trials have revealed that daily treatment with an ICS alone does not delay the long-term decline in FEV_1 in patients with COPD.[75]

In recent years, the concept of “precision medicine” and the need to identify different COPD subtypes based on groups of observable characteristics (ie, phenotypes) and underlying pathophysiologic mechanisms (ie, endotypes) has been explored.[76] Biomarkers are used to identify endotypes[77] and serve as an indicator of normal and pathogenic processes, or pharmacologic responses to therapy.[1] For example, serum eosinophil is a biomarker that may help predict the likelihood of response to an ICS. According to the GOLD Report, patients with elevated serum eosinophils ≥300 cells/µL and/or those with a history of asthma are most likely to benefit from the addition of

an ICS to the regimen.[1] Combination therapy with an ICS and LABA in a single inhaler is more effective than using an ICS alone in improving lung function and health status and reducing exacerbations.[1,78–83] Patients with moderate-to-very severe airflow obstruction who continue to experience symptoms and frequent exacerbations despite dual therapy may benefit from triple therapy (ICS/long-acting antimuscarinic [LAMA]/LABA).[1] Thus, both serum eosinophils and exacerbation history should be considered when determining the likelihood of patient response to ICS therapy.[1,84]

Most trials to date involving ICS therapy have studied patients on moderate-to-high doses. Common adverse effects include oral candidiasis, dysphonia, and skin bruising. ICS either alone or in combination with a bronchodilator may increase the risk of pneumonia in some patients. However, risk estimates have varied owing to inconsistencies in how pneumonia is defined, reported, and diagnosed among trials.[85] Of note, withdrawal from ICS therapy has led to exacerbations in some patients, while other studies have conflicting results.[1] Magnussen and colleagues found a slight decrease in lung function with no increases in exacerbation risk among patients with moderate-to-severe COPD when the ICS dose was tapered over a 3-month period.[86] In a separate study, most patients were able to de-escalate triple therapy to dual bronchodilator therapy without diminished lung function or increased number of exacerbations.[87] However, a greater decline in lung function and increase in exacerbations were observed in patients with elevated serum eosinophil counts (≥300 cells/μL).[87] Given the paucity of data, patient symptoms and lung function should be monitored while gradually stepping down therapy in appropriate candidates.[1]

INITIAL PHARMACOLOGIC THERAPY BY DISEASE SEVERITY

Recent iterations of the GOLD Report now separate "initial pharmacologic management" using the ABCD assessment system from "follow-up pharmacologic treatment," which is based on certain treatable traits and overall response to the initial treatment plan.[1] Patients with infrequent or intermittent symptoms who are at a low risk for a future COPD exacerbation (group A) may be initiated on either a short- or long-acting bronchodilator. As the disease progresses and patients become more symptomatic, as-needed use of bronchodilators alone will not maintain adequate relief from symptoms. Long-acting bronchodilators have been shown to be more effective and convenient for patients experiencing more persistent symptoms. These patients may also continue to use a short-acting bronchodilator as needed for additional symptomatic relief. Combination therapy is generally indicated for patients presenting with more severe symptoms and activity limitation.[1,84] Dual bronchodilator therapy has been shown to improve lung function and symptoms and may reduce exacerbations over monotherapy,[1] likely due to complimentary effects associated with targeting bronchoconstriction through two distinct mechanisms.[58]

CHRONIC OBSTRUCTIVE PULMONARY DISEASE EXACERBATION

An exacerbation of COPD is defined as "an acute worsening of respiratory symptoms that results in additional therapy."[1] Acute exacerbations of COPD are important events in the natural history of this disease.[88,89] Acute exacerbations are associated with considerable morbidity, whereas severe exacerbations are associated with an increased mortality.[89] Furthermore, acute exacerbations are responsible for a high percentage of the health care costs associated with COPD.[1,2]

The cause of acute exacerbations is believed to be a result of respiratory tract infections, either viral or bacterial; air pollution; or

other environmental exposures.[90,91] These triggers can initiate increased bronchospasm and airway resistance in an individual with already compromised lung function. Although mild exacerbations may be readily managed with outpatient therapy, severe exacerbations can result in respiratory failure and death, particularly if they occur in a patient with severe COPD.

Key therapeutic interventions for acute COPD exacerbations include regular bronchodilator therapy, a short course of systemic corticosteroid therapy, antibiotics, and supportive measures such as oxygen therapy. Bronchodilator therapy consisting of a short-acting β_2-agonist with or without a short-acting anticholinergic is given as needed by MDI or nebulizer every 3 to 4 hours.

For videos that show proper use of many types of inhalers, go to **http://use-inhalers.com/** or **http://www.nationaljewish.org/healthinfo/multimedia/asthma-inhalers.aspx**. For a video of how to use a nebulizer, go to **http://www.nationaljewish.org/healthinfo/medications/lung-diseases/devices/nebulizers/instructions.aspx**.

Systemic corticosteroids shorten recovery time and improve lung function and hypoxemia when added to other treatments used to manage exacerbations.[1] Although there are insufficient data to support the optimal duration of treatment, a 5-day course of prednisone has been shown as effective as a 14-day course for reducing the occurrence of a reexacerbation within a 6-month follow-up period.[74] Elevated serum eosinophil levels may predict response to oral corticosteroid therapy, but further study is needed.[1,92] Corticosteroids may be administered either orally or intravenously for severe COPD exacerbations managed in the hospital setting, because there is insufficient evidence to support one method of administration over another.[1,4] No significant difference in length of hospitalization, treatment failure, and hospital readmissions has been observed.[4,92]

Decisions about antibiotic use in the setting of an acute exacerbation should be made based on the presence of the following respiratory symptoms: increased dyspnea, sputum volume, and sputum purulence. Data suggest that if two of the three are increased, antibiotics are beneficial.[93] The optimal antibiotic regimen for acute COPD exacerbations has not been rigorously studied. For many outpatients, however, generic, low-cost antibiotics, including amoxicillin, trimethoprim–sulfamethoxazole, or doxycycline, may be very effective. Indeed, these agents can effectively cover the most common bacterial causes of acute exacerbations, including *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Guidelines suggest that hospitalized patients with respiratory failure should receive broad-spectrum antimicrobials that include activity against *Pseudomonas aeruginosa*, because these patients have a higher risk for more resistant organisms.[1,94]

CHRONIC OBSTRUCTIVE PULMONARY DISEASE GROUP A (LOW RISK, LESS SYMPTOMS)

Diagnosis

CASE 19-1

QUESTION 1: T.A., a 51-year-old White male smoker, presents with daily cough and mild dyspnea on exertion with strenuous activity. He has noticed that walking up two flights of steps bothers him, when previously it did not. He has had a slight amount of wheezing, but no chest pain. He has no known chronic medical problems. He has smoked 1.5 packs/day for 34 years, and he continues to smoke that amount. His physical examination is unremarkable. COPD is suspected.

What diagnostic test should be ordered?

A clinical diagnosis of COPD should be considered in any patient presenting with persistent dyspnea, chronic cough, or sputum production with a history of exposure to risk factors such as cigarette smoking. Spirometry is the gold-standard diagnostic test and should be considered to confirm the diagnosis of COPD. The main values gleaned from spirometry will include FVC, FEV_1, and FEV_1/FVC ratio. An FEV_1/FVC ratio of <0.70 following a bronchodilator indicates obstruction to expiratory flow consistent with COPD. The FEV_1 can be used in conjunction with other clinical indicators to further determine disease severity. Repeat spirometry on a separate occasion is recommended when the postbronchodilator FEV_1/FVC ratio falls between 0.6 and 0.8, as the ratio may change as a result of biologic variation.[1]

CASE 19-1, QUESTION 2: Office spirometry demonstrates a postbronchodilator FEV_1/FVC of 0.59 and an absolute FEV_1 of 81% of predicted. T.A. has a CAT score of 7 and has had one exacerbation in the past year, which was managed at home. Using GOLD criteria, which initial COPD risk group should T.A. be assigned, and what other diagnostic tests would be necessary before initiating therapy?

Based on GOLD guidelines, this patient has clinical features most consistent with "group A." A CXR study may be performed to exclude other respiratory diagnoses contributing to the patient's symptoms; however, the abnormal spirometry, persistent symptoms, and significant exposure to cigarette smoke (51 pack-year history of smoking) are sufficient to make the diagnosis of COPD and to initiate therapy.[22]

In certain cases of diagnostic uncertainty or in patients with severe disease being considered for surgical intervention, such as lung volume reduction surgery, a complete set of pulmonary function tests, including the determination of lung volumes and DLCO, may be performed.

In patients with more severe symptoms or airflow obstruction, assessment of oxygen status by means of pulse oximetry or ABG

may be necessary. Pulse oximetry should be used to assess stable patients if the FEV_1 is <35% of predicted or with clinical signs suggestive of respiratory failure or right-sided heart failure. ABGs are recommended if peripheral saturation is <92%.[1] An α_1-antitrypsin level to rule out AATD is generally recommended for all individuals with COPD.[1,32] Especially those with early onset of disease (younger than 45 years), or in patients with a strong family history of COPD.[1]

CASE 19-1, QUESTION 3: What therapeutic interventions should be recommended for T.A. at this point?

Therapeutic Management

SMOKING CESSATION

A comprehensive smoking cessation plan with therapy should be initiated for T.A. because smoking cessation has been shown to decrease the decline in FEV_1 associated with COPD.[1,28] Although pharmacologic interventions for smoking cessation are covered elsewhere in the text (see Chapter 91, Tobacco Use and Dependence), it should be noted that a personalized message may be beneficial for this patient. Indeed, discussion of spirometry results with the patient can provide an important opportunity to deliver a personalized message.[95] It can be explained to T.A. that he is beginning to develop definite irreversible abnormalities in his pulmonary function and, therefore, is a "susceptible" smoker. It is critical for him to stop smoking and, thereby, prevent continued deterioration in lung function.

IMMUNIZATIONS

In addition to smoking cessation, this patient's immunization status should be evaluated.[96] According to the GOLD Report and in the absence of contraindications, T.A. is a candidate for vaccination against influenza and pneumococcal pneumonia, even though he is in the early stages of COPD.[1] Patients with COPD are at risk for

increased morbidity and mortality if they develop either of these infectious complications.

Individuals at highest risk for significant morbidity and mortality from influenza and pneumonia are those with chronic disease, including lung disease. Optimally, the influenza vaccine should be administered during the fall before the end of October.[97] This allows an adequate antibody response before the peak influenza season, which typically occurs within the first quarter of the year. Annual immunization is required to ensure adequate antibody protection against influenza virus and is effective in reducing morbidity and mortality from influenza.[94]

The pneumococcal polysaccharide vaccine (Pneumovax 23, PPSV23) is also recommended for patients with COPD.[1] The PPSV23 contains 23 *S. pneumoniae* serotypes and provides protection against *S. pneumoniae*.[98] PCV13 (Prevnar-13) may further protect against PCV13-type pneumonia and invasive pneumococcal disease in adults age 65 years or older without an immunocompromising condition, a cerebrospinal fluid (CSF) leak, or cochlear implant.[1,99] The Advisory Committee on Immunization Practices (ACIP) now recommends only adding the PCV13 following shared clinical decision-making between the patient and clinician.[99] These vaccines should be separated as indicated to ensure an optimal immune response.[100] To manage T.A.'s symptoms, treatment with an as-needed bronchodilator may be reasonable to start. Bronchodilators are the primary pharmacologic therapy used in the management of COPD.[1,22]

Available bronchodilator therapies include short-acting β_2-agonist or LABA, short- or long-acting anticholinergics, and methylxanthines (theophylline). For initial treatment, the most common choice for T.A. would be a short-acting inhaled β_2-agonist (eg, albuterol), a short-acting inhaled anticholinergic (eg, ipratropium), or a combination of these two agents. Either of these therapies has a relatively short onset of action and is effective in relieving symptoms. **Table 19-3** summarizes inhaled therapeutic options for COPD.

SHORT-ACTING β_2-AGONISTS

β_2-Agonists produce bronchodilation by relaxing bronchial smooth muscle through activation of cyclic adenosine monophosphate (cAMP).[101] The inhalation route of delivery for bronchodilators is recommended over oral therapy based on safety and efficacy. The dose–response curve among all available bronchodilators is relatively flat and similar. No evidence suggests that one agent is superior to another.

Albuterol is the most frequently used agent in this class. It is available as an MDI or DPI 90 µg/inhalation. It is also available as a premixed solution for nebulization (eg, adult dose 2.5 mg/0.5 mL), as well as a concentrated solution (5 mg/mL, 0.5%) that requires saline to be prescribed separately. The onset of action of short-acting β_2-agonists (eg, albuterol, levalbuterol) is rapid (within 5 minutes) and generally reaches maximal effect in 15 to 30 minutes. The duration of action is ~4 hours. Although inhaled β_2-agonists are usually well tolerated, some patients experience adverse effects (tremors, tachycardia, or nervousness) with even low dosages. Although concern has been expressed about the safety of short-acting inhaled β_2-agonists in patients with cardiac disease, a cohort study using the Saskatchewan Health Services database concluded that there was no increased risk for fatal or nonfatal myocardial infarction in patients using these agents.[102]

SHORT-ACTING ANTICHOLINERGICS

The parasympathetic (cholinergic) nervous system plays a primary role in the control of bronchomotor tone in COPD. By inhibiting cyclic guanosine monophosphate (cGMP) in the lung, aerosolized anticholinergic drugs are effective bronchodilators. The bronchodilation produced by anticholinergics in patients with stable COPD has been shown to be noninferior to that achieved by inhaled β_2-agonists.

Ipratropium bromide is the primary short-acting anticholinergic agent used in COPD. It is marketed as both an MDI (17 µg ipratropium

per puff) and as a solution for nebulization (0.5 mg ipratropium/2.5 mL). Ipratropium has an average onset of effect within 15 minutes, with a maximal bronchodilator effect in 60 to 90 minutes, although some patients may experience more rapid symptom relief. The duration of action is ~6 hours. Although some reports suggest a quicker onset of action, patients should be advised that the relief of acute symptoms will be slower compared with an inhaled β_2-agonist. A typical dose of ipratropium is two inhalations four times daily.[103] Although well tolerated, some patients experience dry mouth, nausea, and blurred vision with the use of ipratropium.

The anticholinergic actions of ipratropium are localized predominantly in the lungs, with an apparent specificity of action in the larger airways. Because it has minimal effects on sputum viscosity, there is little problem with drying of airway secretions. In addition, ipratropium's structure as a quaternary amine increases its polarity, thereby minimizing absorption from the lung and systemic side effects. These structural properties also reduce penetration across the blood–brain barrier, reducing the incidence of confusion and other central nervous system (CNS) side effects.

COMBINATION β_2-AGONISTS–ANTICHOLINERGICS

Combination therapy with two different classes of bronchodilators is appealing because it may decrease the cumulative dose of individual agents, thereby decreasing the risk of side effects while maintaining the benefits of each medication. In addition, anticholinergics and β-agonists have different mechanisms of action, and combining these two classes may provide additional benefit. Indeed, it has been demonstrated that combination therapy results in significantly greater increases in FEV_1 compared with the use of either albuterol or ipratropium alone.[104] The Combivent Respimat contains both albuterol and ipratropium in a single inhaler.[105] The respimat is a novel propellant-free inhalation device that produces a slow-moving mist from mechanical energy produced by the release of a compressed spring.

Umeclidinium plus vilanterol (Anoro Ellipta) and tiotropium plus olodaterol (Stiolto Respimat) are once-daily products that combine a long-acting anticholinergic with an LABA in a single device.[106,107] Glycopyrrolate is available in combination with indacaterol (Utibron™ Neohaler) and in combination with formoterol (Bevespi Aerosphere®), but both are dosed twice daily (bid).[108,109] Each has been approved for the maintenance treatment of airflow obstruction in patients with COPD.[106,109]

CHRONIC OBSTRUCTIVE PULMONARY DISEASE WITH DISEASE PROGRESSION

Therapeutic Management

CASE 19-2

QUESTION 1: J.O., a 46-year-old female with a 32-pack-year history of cigarette smoking, presents with increasing shortness of breath. She gets winded walking on level ground after about 100 yards. She quit smoking 2 years ago. The chronic cough that she previously had lessened after smoking cessation, but the dyspnea is now somewhat worse, despite the use of an albuterol inhaler on an as-needed basis. On examination, mild wheezing is noted. A CXR is unremarkable. No history of asthma or atopic conditions and serum eosinophils are unremarkable. Office spirometry demonstrates a postbronchodilator FEV_1/FVC ratio of 0.64 and an absolute FEV_1 of 2.0 L or 60% of predicted. J.O. has a CAT score of 20 and has had one exacerbation in the past year, which was managed at home. Postbronchodilator treatment demonstrated an FEV_1 increase of 100 mL, marking a 5% increase from baseline.

How should J.O. be treated?

J.O. is reporting progression of dyspnea despite smoking cessation and the use of a short-acting β_2-agonist. She is still at a low risk for an exacerbation based on her exacerbation history. Because pharmacologic management of COPD involves a stepwise approach, regular use of a long-acting bronchodilator would be the

next step in treatment, provided J.O. has been using her albuterol inhaler correctly and adherent to her initial treatment plan.

The main classes of long-acting bronchodilators currently available include β_2-agonists and anticholinergics. Both classes can be further divided into two groups according to the duration of activity—those producing bronchodilation for 12+ hours and those producing bronchodilation for 24+ hours. Both classes have been shown to improve quality of life and reduce dyspnea in patients with COPD.

LONG-ACTING β_2-AGONISTS

The role of inhaled LABAs in the chronic management of COPD has become well established in recent years. Available evidence with both salmeterol and formoterol shows improved pulmonary function, reduced dyspnea, and enhanced quality of life in patients with COPD.[1] Indacaterol, olodaterol, and vilanterol are dosed once daily and have a rapid onset of activity (eg, >5 minutes) and produce bronchodilation for 24 hours or more. Their long duration of activity and comparable safety profile may offer an added convenience to some patients. A plateau in bronchodilation is achieved for most patients at the recommended dose for each agent, so no benefits exist in exceeding the recommended dose. In addition, higher doses will increase the risk of adverse events associated with β_2-agonist excess.

LONG-ACTING ANTICHOLINERGICS

Vagal cholinergic tone is a reversible component of the airway limitation in COPD. Stimulation of the vagal parasympathetic nerves causes the release of acetylcholine, which, in turn, binds to muscarinic receptors to produce bronchoconstriction and secretion of mucus. Three muscarinic subtypes have been identified in human airways: M_1, M_2, and M_3 receptors. Tiotropium is a long-acting anticholinergic that binds to the M_1, M_2, and M_3 muscarinic receptors of bronchial smooth muscle.[110] Although tiotropium dissociates rapidly from the M_2 receptor, it dissociates much more slowly from

the M_1 and M_3 receptors. In fact, its dissociation from the M_1 and M_3 receptors is 100 times slower than that of ipratropium. M_1 receptors are located on parasympathetic ganglia, where they facilitate postganglionic transmission, thus enhancing cholinergic tone. M_3 receptors are found on airway smooth muscle and mucous glands, where activation leads to bronchoconstriction and mucus secretion. Conversely, M_2 receptors are located on postganglionic nerve endings, where they serve as autoreceptors regulating acetylcholine release and, thereby, cholinergic tone. Thus, anticholinergics, by virtue of antagonizing M_1 and M_3 receptors, relax airway smooth muscle and can reduce mucus secretion. M_2 blockade, however, augments acetylcholine release and thus enhances cholinergic tone. Therefore, the slower dissociation rate from both the M_1 and M_3 receptors enhances bronchodilation and allows the convenience of once-daily dosing.

Tiotropium has a very long duration of action and can provide effective bronchodilation with once-daily dosing. Numerous studies have documented its beneficial effect on pulmonary function and quality of life. The UPLIFT (Understanding Potential Long-Term Impacts on Function with Tiotropium) compared 4 years of therapy with either tiotropium or placebo in nearly 6000 patients with COPD. Tiotropium was associated with improvements in lung function, quality of life, and exacerbation risk, but did not impact the rate of decline of FEV_1 or mortality.[61] Tiotropium is also a quaternary amine with limited systemic absorption; therefore, the agent is well tolerated, with dry mouth being the major side effect. Concerns have been raised, however, about tiotropium's safety. In particular, disparate sources have identified stroke, cardiovascular events, and death as possible adverse outcomes. After completion of UPLIFT, which included 17,721 patient-years of drug exposure, the Food and Drug Administration (FDA) concluded that the appropriate use of tiotropium in COPD patients does not place them at increased risk for stroke or adverse cardiovascular events.[111] In September 2014, tiotropium was also approved to be delivered via the Respimat

device. The Tiotropium Safety and Performance in Respimat (TIOSPIR) trial is the largest COPD trial to date involving >17,000 patients. This trial was designed to directly compare the safety of tiotropium respimat to tiotropium delivered via the HandiHaler device. The length of time to first COPD exacerbation was also followed to compare efficacy. Both the Respimat and HandiHaler were found to have comparable results for exacerbation frequency, as well as exacerbations associated with hospitalization. The incidence of adverse events was also similar between all treatment groups.[112]

Aclidinium bromide (Tudorza PressAir), umeclidinium bromide (Incruse Ellipta), and glycopyrrolate (Seebri Neohaler) are other long-acting anticholinergics approved for the long-term maintenance treatment of COPD. These agents have been shown to improve lung function and are well tolerated.[113–115]

J.O. should be started on a long-acting bronchodilator, such as salmeterol or tiotropium. Once-daily β-agonists such as indacaterol or olodaterol are additional options to consider. Recently approved anticholinergics such as aclidinium bromide, glycopyrrolate, or umeclidinium bromide are other potential options. It should be noted that the tolerability and efficacy of the available long-acting bronchodilators are comparable. The choice of agent is largely based on considerations such as the frequency of drug administration, the patient's ability to use the inhalation device correctly, and any out-of-pocket costs incurred by the patient. J.O. should also be instructed to continue her albuterol two puffs every 4 hours as needed for breakthrough symptoms. A follow-up visit should be scheduled to assess her response.

CASE 19-2, QUESTION 2: J.O. is started on tiotropium respimat, inhale 5 μg daily and returns to the office for a follow-up visit 3 months later. She has had significant benefit from the medication and has had decreased wheezing and a noticeable improvement in her exercise tolerance. She asks to have spirometry repeated to see whether her lung function has improved on the new medication. Spirometry is repeated, and no significant improvement is noted in her FEV_1.

How can she feel better, with improved exercise tolerance, without an improvement in her lung function?

Increasing evidence suggests that bronchodilators, including LABAs and anticholinergics, may reduce exercise-related dyspnea in patients with COPD by decreasing dynamic hyperinflation.[116] This improvement may be independent of marked changes in spirometry performed at rest. Indeed, because of flow limitation, these patients who exercise can have significant worsening of air trapping, which can worsen lung compliance and adversely affect respiratory muscle mechanics. A number of studies have shown that alleviation of such dynamic hyperinflation may be an important mechanism whereby bronchodilators improve exercise tolerance in patients with obstructive lung disease.[116]

CASE 19-2, QUESTION 3: J.O. seemed to do reasonably well for a number of years, but now, 3 years later, she has noticed progressive dyspnea on exertion. She is now having difficulty carrying laundry up from her basement, and she has noticed that her overall activity level has been curtailed. Repeat office spirometry now shows an FEV_1/FVC ratio of 0.49 and an absolute FEV_1 of 49% of predicted. She now has a CAT score of 22 and has had two exacerbations in the past year. J.O. has been adherent with her tiotropium regimen and has had no other significant changes to her medical history. She remains smoke free and is not exposed to secondhand smoke in her home and work environments. What therapeutic intervention(s) should be considered at this point?

INHALED CORTICOSTEROID THERAPY

J.O. has had significant deterioration in status and repeated COPD exacerbations despite appropriate adherence to tiotropium. Before modifying therapy, proper inhaler technique, medication adherence, and impact of nonpharmacologic interventions should be assessed. Combination therapy with either LAMA + LABA or ICS + LABA should be considered in patients with persistent symptoms or who continue to experience exacerbations despite appropriate use and adherence to long-acting bronchodilator monotherapy.[1] Fixed-dose combination products are preferred, and several options are commercially

available (Table 19-3). LAMA + LABA therapy may be preferred, given the absence of asthma or atopic conditions and without elevated serum eosinophil levels and other biomarkers associated with ICS response. Also, dual bronchodilator therapy has a lower incidence of pneumonia, when compared to regimens containing an ICS. An LAMA + LABA combination was superior to an ICS + LABA in preventing exacerbations and other patient-reported outcomes in those with a history of prior exacerbations.[117] Several corticosteroid LABA inhalers are available and indicated for COPD, including Advair (fluticasone–salmeterol), Symbicort (budesonide–formoterol), and Breo Ellipta (fluticasone–vilanterol). No convincing data suggest that one preparation is superior to the other in the treatment of COPD. However, a number of multicenter, randomized, controlled clinical trials have demonstrated the efficacy of ICS in COPD.[78,83] The data have supported the use of ICS in advanced COPD and in patients with frequent exacerbations. ICS responsiveness may be further predicted by the presence of elevated eosinophils (≥300 cells/μL) or underlying asthma.[1] Moreover, regular use of ICS can decrease the frequency of acute exacerbations and improve health-related quality of life in patients with an FEV_1 <60% of predicted.[22]

Table 19-3
Inhaled Therapeutic Options for COPD

Medication Brand Name and Strength (per Inhalation)	Chemical Name	Device	No. of Doses[a]/Device or Box
Short-Acting β_2 Agonists			
[c]ProAir HFA 90 µg, [c]Proventil HFA 90 µg, [c]Ventolin HFA 90 µg	Albuterol	MDI	200[b]
ProAir, RespiClick 90 µg	Albuterol	DPI	200
[c]AccuNeb 0.63 mg/3 mL, 1.25 mg/3 mL	Albuterol	Nebulizer	Varies
ProAir® Digihaler™	Albuterol	DPI	200
[c]Proventil 2.5 mg/3 mL (0.083%),[e]5 mg/mL (0.5%) *concentrate*	Albuterol	Nebulizer	Varies
[c]Xopenex HFA 45 µg	Levalbuterol	MDI	200[b]
[c]Xopenex 0.31 mg/3 mL, 0.63 mg/3 mL, 1.25 mg/3 mL, [e]1.25 mg/0.5 mL *concentrate*	Levalbuterol	Nebulizer	Varies
Short-Acting Anticholinergic			
Atrovent HFA 17 µg	Ipratropium	MDI	200[b]
[c]Atrovent 0.02% (0.5 mg/2.5 mL) vial	Ipratropium	Nebulizer	25ct, 30ct, 60ct
Short-Acting Anticholinergic + β_2-Agonist Combination			
Combivent Respimat 20–100 µg	Ipratropium + Albuterol	SMI	120[b]
[c]DuoNeb 0.5–2.5 mg/3 mL vial	Ipratropium + Albuterol	Nebulizer	30ct, 60ct
Long-Acting β_2-Agonists			
Serevent Diskus 50 µg	Salmeterol	DPI	60
Brovana 15 µg/2 mL vial	Arformoterol	Nebulizer	30ct, 60ct
Perforomist 20 µg/2 mL vial	Formoterol	Nebulizer	30ct, 60ct
Arcapta Neohaler 75 µg	Indacaterol maleate	DPI	30 blister units
Striverdi Respimat 2.5 µg	Olodaterol	SMI	60[b](*30 doses*)
Long-Acting Anticholinergics			
Spiriva HandiHaler 18 µg	Tiotropium	DPI	30 blister units
[d]Spiriva Respimat 2.5 µg	Tiotropium	SMI	60[b](*30 doses*)
Tudorza Pressair 400 µg	Aclidinium bromide	DPI	60
Incruse Ellipta 62.5 µg	Umeclidinium	DPI	30
Seebri Neohaler 15.6 µg	Glycopyrrolate	DPI	60 blister units
Lonhala Magnair 25 µg/mL	Glycopyrrolate	Nebulizer	60ct
Yupelri 175 µg/3 mL	Revefenacin	Nebulizer	30ct
Long-Acting Anticholinergic + β_2-Agonist Combination			
Anoro Ellipta 62.5–25 µg	Umeclidinium + Vilanterol	DPI	60
Stiolto Respimat 2.5–2.5 µg	Tiotropium + Olodaterol	SMI	60[b](*30 doses*)
Utibron Neohaler 15.6–27.5 µg	Glycopyrrolate + Indacaterol	DPI	60 blister units
Bevespi Aerosphere 9–4.8 µg	Glycopyrrolate + Formoterol	MDI	120[b]
Duaklir Pressair 400–12 µg	Aclidinium + Formoterol	DPI	60
Inhaled Corticosteroid + Long-Acting β_2-Agonist Combination			
[c,d]Advair Diskus 250–50 µg	Fluticasone + Salmeterol	DPI	60
[c,d]Symbicort HFA 160–4.5 µg	Budesonide + Formoterol	MDI	120[b]
[d]Breo Ellipta 100–25 µg	Fluticasone + Vilanterol	DPI	60
Inhaled Corticosteroid + Long-Acting Anticholinergic + β_2-Agonist Combination			
[b,d]Trelegy Ellipta 100-62.5-25 µg	Fluticasone furoate + umeclidinium + vilanterol	DPI	60
Breztri Aerosphere 160-9-4.8 µg	Budesonide + glycopyrrolate + formoterol	MDI	120[b]

DPI, dry-powder inhaler; MDI, metered-dose inhaler; SMI, soft mist inhaler.

[a]Generic formulations available.

[c]Institutional sizes not included.

[d]Number of doses after initial priming.

[e]Nebulized solutions marked “0.5- mL concentrate” should be diluted with 0.9% sodium chloride solution.

The TORCH study has defined the benefits and potential side effects of ICS in a broader patient population of COPD.[57] In this multicenter, randomized, placebo-controlled study, mean FEV_1 was 50% of predicted, but entry criteria did not require a history of repeated exacerbations. More than 6000 patients were randomly assigned to either an ICS (fluticasone 500 µg bid), inhaled salmeterol (50 µg bid), combined fluticasone 500 µg and salmeterol 50 µg bid, or placebo. Subjects were assessed for ~3 years. A significant benefit was seen as measured by decreased exacerbation rates in subjects taking either inhaled fluticasone or a combination of fluticasone–salmeterol therapy. Also, an improvement was found in mortality with combination therapy that approached, but did not reach statistical significance. Overall adverse side effects with ICS were similar to those with placebo. An increased risk, however, was seen for lower respiratory tract infections with inhaled fluticasone or fluticasone–salmeterol. Of note, patients did not experience an increased risk of ocular manifestations or decreased boFFIgurene density with ICS treatment.

J.O. is already taking tiotropium, so a decision must be made regarding step-up therapy. Proper inhalation technique and adherence should be confirmed before escalating therapy. LAMA + LABA is the preferred regimen for this patient, given her persistent symptom burden and high frequency of exacerbations over the past year despite LAMA monotherapy. Tiotropium + olodaterol is one possible fixed-dose combination product that may replace tiotropium. J.O. is already familiar with the Respimat device, which may help maintain adherence. If J.O. is experiencing difficulty with using the respimat, several alternative long-acting dual bronchodilator products are available in different inhaled delivery devices.

CASE 19-2, QUESTION 4: J.O. calls the next day, having read something on the Internet regarding possible increased risk of death in people with obstructive

lung disease who take long-acting bronchodilators. She is reluctant to take it. What should you tell her?

SAFETY OF LONG-ACTING BRONCHODILATORS

Although some evidence in asthma indicates that the use of long-acting bronchodilators may be associated with an increased risk of death, such evidence does not exist in patients with COPD. In fact, the TORCH study demonstrated no increased risk of death or adverse events among patients prescribed salmeterol compared with placebo.[57] Other trials designed to evaluate the safety of bronchodilator use have resulted in similar findings.[61,62,102,111] The patient should be reassured that long-acting bronchodilators are safe in COPD.

PULMONARY REHABILITATION

CASE 19-2, QUESTION 5: J.O. also wonders whether anything else other than her medication can be done for her. What advice might be given?

At this point, pulmonary rehabilitation should be strongly considered. In fact, a comprehensive multidisciplinary pulmonary rehabilitation program should be considered in any patient with COPD experiencing persistent shortness of breath despite pharmacologic management.[1,46]

Increasing evidence points to COPD as a systemic process,[118] and pulmonary rehabilitation addresses the systemic nature of the disease. Although the proximate cause of disability involves the respiratory system, leading to dyspnea on exertion, this, in turn, has systemic consequences. Although the changes may be fairly subtle to start with, most patients will gradually manifest increasing limitations in their activity. This results in substantial deconditioning. It is likely that this deconditioning, in addition to other factors such as systemic inflammation, adversely affect skeletal muscle function. Indeed, evidence is clear that oxidative capacity is diminished in patients with COPD,[47–49] which results in overall decreased aerobic

capacity and increased lactic acid production for a given level of activity.[50] The increased acid load will lead to a greater requirement for ventilation, which makes dyspnea more severe. The more dyspneic the patient is, the less activity he or she will do, leading to more deconditioning and recapitulation of the downward spiral.

Pulmonary rehabilitation is an exercise-based, multidisciplinary program that seeks to address this cycle.[1] Most programs generally last 8 to 12 weeks and involve two to three sessions per week.[46] Education, particularly about medication use, as well as psychosocial counseling and breathing retraining are important components of the program. An important component of breathing retraining involves coaching patients how to use pursed-lip breathing effectively. Pursed-lip breathing involves pursing the lips together (as in whistling) during exhalation. This helps to slow down respirations and also provides a back pressure in the small airways, preventing dynamic airway collapse and exercise-induced hyperinflation. The major intervention, however, is exercise training, especially endurance training of the lower extremities (eg, using a treadmill or bicycle ergometer). Numerous studies have demonstrated that a rehabilitation program can significantly improve exercise capacity and quality of life, as well as decrease health care utilization.[51] This may partly be related to the beneficial effects of exercise on the oxidative capacity of the skeletal muscles.

J.O. should be referred to a local outpatient pulmonary rehabilitation program. A typical program involves 2-hour sessions, two to three times per week for 8 to 12 weeks. The sessions will involve education, breathing retraining, and strength and endurance exercise training.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE WITH DISEASE PROGRESSION

Acute Exacerbation of Chronic Obstructive Pulmonary Disease

ANTIMICROBIAL THERAPY

CASE 19-3

QUESTION 1: R.L., a 66-year-old male with diabetes mellitus and severe COPD, presents with increased cough with productive discolored sputum after a "cold." He had been hospitalized 6 weeks earlier with community-acquired pneumonia. He is a former smoker (quit 10 years ago); his current medications include tiotropium respimat 5 µg once daily, albuterol MDI two puffs every 4 hours as needed, and theophylline 200 mg bid. He also has increased dyspnea and chest tightness. On examination, he is in no acute distress and vital signs are stable. There is increased wheezing on chest examination, and the rest of the examination is unchanged. Room air pulse oximetry is 90%, and a CXR in the office shows no infiltrates.

How should this patient be treated?

This patient has increased sputum purulence and increased dyspnea consistent with an exacerbation of COPD. It is not uncommon for such an exacerbation to be triggered by an upper respiratory viral infection. Procalcitonin is a biomarker more specific for bacterial infections and has been used to guide decisions involving antibiotic use.[1] However, the test is relatively expensive, and the clinical effectiveness of procalcitonin-guided therapy requires further study.

Given that the patient has increased dyspnea and purulent sputum production, a course of systemic corticosteroids (eg, 40 mg of prednisone daily for 5 days) and a course of antibiotics are warranted. In outpatients with low-risk factors, a low-cost antibiotic regimen is a reasonable option. Empirical treatment with an aminopenicillin with or without clavulanic acid, a macrolide, or tetracycline derivative such a doxycycline may be used.[1] Although other antibiotics are commonly prescribed, no data support superiority in this setting when compared with conventional, less expensive agents. An acute exacerbation of COPD is one of the few

instances in which antibiotic therapy is warranted to treat a respiratory infection in the absence of evidence of lower respiratory tract involvement (ie, pneumonia).

Patients with COPD and risk factors for poor outcome (severe COPD, comorbid conditions, history of frequent exacerbations) may be more susceptible to resistant pathogens. As such, guidelines recommend that a broad-spectrum antibiotic regimen be considered, including β-lactam–β-lactamase inhibitor combinations, quinolone antibiotics, or second- or third-generation cephalosporins.[1,94]

Because of his recent hospitalization, R.L. is at increased risk for resistant pathogens, including *P. aeruginosa*. He also presents with increased sputum purulence and increased dyspnea, so a broad-spectrum antimicrobial regimen, such as oral ciprofloxacin 750 mg bid or oral levofloxacin 500 mg every day for 5 to 10 days, would be appropriate. A course of oral prednisone 40 mg daily for 5 days is also indicated to improve R.L.'s lung function, reduce his hypoxemia, and hasten his recovery time.

CASE 19-3, QUESTION 2: R.L. was treated with oral ciprofloxacin 750 mg bid and demonstrated a decrease in sputum volume and purulence with less dyspnea after 3 days of therapy. However, 5 days later, he is feeling palpitations and has become nauseous. What laboratory value should be checked?

This patient has clinical evidence of theophylline toxicity. Adverse gastrointestinal reactions (eg, nausea) and CNS symptoms, including sleep difficulty and nervousness, are consistent with theophylline toxicity. Other adverse reactions associated with methylxanthines are cardiac irritability (tachycardia or arrhythmias) and seizures. All these side effects are dose related. Gastrointestinal intolerance, nervousness, and insomnia can occur at any serum concentration, but increase in frequency when serum concentrations are >15 μg/mL.

In R.L., the addition of the antibiotic ciprofloxacin to his regimen most likely resulted in a drug interaction, causing a rise in his theophylline concentration. The potential for an interaction with theophylline varies among the available fluoroquinolone antibiotics.

Drug interactions are dependent on several factors, including the dose of each agent and the baseline serum theophylline concentration. Elevations in the theophylline concentration of 25% are typical with ciprofloxacin interactions, although elevations of 50% have been observed. In R.L., a theophylline concentration should be obtained and further doses withheld until results are known.

In general, theophylline metabolism is associated with significant interpatient and intrapatient variability. Patients should be monitored closely for early signs of toxicity, as well as for the initiation of drugs that potentially may interact. Understanding and recognizing the potential for drug interactions can allow safe and effective therapy with theophylline.

CASE 19-3, QUESTION 3: A theophylline serum concentration is measured for R.L. It is reported as 21 μg/mL. What action should be taken?

The serum concentration is consistent with the interaction between theophylline and ciprofloxacin reported in the literature. His symptoms do not appear life-threatening at this point, so a conservative approach to treatment is appropriate. Theophylline should be withheld for one dose and then restarted at a lower dose (100 mg bid) until the ciprofloxacin therapy is completed. Alternatively, theophylline could be withheld until the antibiotic treatment is finished or discontinued. As mentioned, theophylline has a narrow therapeutic index and has the potential for serious toxicity as is evidenced by the current case. If the patient is unclear how beneficial the theophylline has been, a trial off of the medication is reasonable. After ~2 to 4 weeks, R.L. should be reassessed. If he feels that his chronic symptoms are no different without the drug, it should be discontinued. On the other hand, his symptoms may become more pronounced without the theophylline, and it could then be restarted. Alternatively, it would be reasonable to replace theophylline with an additional long-acting bronchodilator from a different class; in this case, a long-acting β-agonist. Evidence suggests that the combination of a long-acting anticholinergic and

LABA can increase lung function and reduce hyperinflation compared with either agent used alone.[119,120] Salmeterol, indacaterol, and olodaterol are possible stand-alone long-acting β-agonist options. In addition, formoterol and arformoterol are available in a nebulized solution. However, fixed-dose dual bronchodilator combination products may be easier for R.L. to adhere to.

COPD has a progressive course, highlighted by a worsening of symptoms with time. Because stepwise therapy is recommended, it is not uncommon to find patients on multiple medications added on in an attempt to alleviate symptoms. Nevertheless, it is important periodically to assess the patient to determine whether all the medications are continuing to provide symptomatic benefit and are still needed. This may result in a step-down approach.

Oxygen Therapy

CASE 19-4

QUESTION 1: P.J., a 62-year-old male with long-standing COPD, presents with worsening dyspnea on exertion. He is currently prescribed combination fluticasone–salmeterol (Advair 250/50 one puff bid), tiotropium (Spiriva 18 μg one puff every day), and as-needed albuterol (two to four puffs every 4 to 6 hours as needed). P.J. reports excellent adherence with his medications, and an evaluation of his inhaler technique reveals he is able to use all three devices correctly. He has undergone pulmonary rehabilitation in the past with some benefit. He is no longer exercising, however. He has smoked 1.5 packs of cigarettes a day for 40 years (60 pack-years), but quit 1 year previously. His most recent FEV_1/FVC ratio is 0.41, and his FEV_1 is 1.25 L or 38% of predicted. His room air oxygen saturation at rest is 85%. On examination, reduced breath sounds are noted in his chest, and he has lower extremity edema. His physician recommended supplemental oxygen; however, he is resistant.

How might P.J. benefit from supplemental oxygen?

The Nocturnal Oxygen Treatment Trial (NOTT), a randomized controlled study, studied patients with COPD and severe hypoxemia ($Pa_{O_2} \leq 55$ mm Hg, or $Pa_{O_2} \leq 59$ mm Hg associated with polycythemia or peripheral edema).[40] Patients were randomly

assigned to receive continuous oxygen or nocturnal oxygen. The primary outcome variable was mortality. Subjects using continuous oxygen had a significantly greater survival and improved end-organ function, including improved cognitive function. The Medical Research Council Study published in 1981, using similar entry criteria, demonstrated a significant survival benefit with continuous supplemental oxygen compared with no oxygen.[41]

On the basis of these studies, long-term oxygen administration (>15 hours/day) has been shown to improve survival in patients with severe resting hypoxemia (PaO_2 ≤ 7.3 kPa [55 mm Hg] or SaO_2 ≤ 88%), when confirmed twice over a 3-week period.[1] Individual patient factors should be considered before prescribing long-term oxygen supplementation in patients with stable COPD who experience mild-to-moderate desaturation while at rest or during exercise.[1] These guidelines (**Table 19-4**) are used by Medicare and most insurance companies as criteria to determine coverage for supplemental oxygen.[121] This patient should be encouraged to use supplemental oxygen titrated to a target saturation of ≥90% for maintenance, because it is one of the few available interventions that has been associated with improved survival in COPD.[1] In addition, a fixed-dose inhaled LAMA + LABA + ICS option (ie, triple therapy), such as Breztri™ Aerosphere™, or Trelegy® Ellipta®, may further simplify the regimen.

Table 19-4

Guidelines for Insurance Reimbursement of Oxygen Therapy in Chronic Obstructive Pulmonary Disease (COPD)

Severe hypoxemia at rest[a]:
PaO_2 ≤ 55 mm Hg
Or
PaO_2 ≤ 59 mm Hg, with polycythemia or evidence of cor pulmonale
Or
Oxygen saturation ≤ 88%
Oxygen desaturation ≤ 88% with activity or during sleep[b]

[a]Proven to improve survival.

[b]Efficacy not proven.

In addition to supplemental oxygen, the patient should be reenrolled in pulmonary rehabilitation. As mentioned, existing data suggest that this intervention can improve quality of life and exercise tolerance and decrease health care utilization.

Surgical Treatments for Chronic Obstructive Pulmonary Disease

CASE 19-4, QUESTION 2: P.J. is prescribed supplemental oxygen and enrolls in a pulmonary rehabilitation program. These interventions are successful in improving exercise tolerance; however, he presents 12 months later with worsening dyspnea. In addition, although he is compliant with the oxygen, he is wondering whether any other interventions available might improve his lung function and allow him to "get off" of oxygen.

He is reevaluated with pulmonary function studies, which demonstrate a reduced FEV_1/FVC ratio of 0.38 and an absolute FEV_1 of 29% of predicted. In addition, lung volume determinations show severe hyperinflation (TLC = 135% of predicted and air-trapping RV = 292% of predicted). His CXR shows a marked decrease in lung markings in the upper lung zones with vascular crowding in the lower lung fields. What therapeutic options are available for P.J.?

Lung volume reduction surgery, which involves the surgical removal of ~30% of the volume of each lung, can significantly improve quality of life, exercise tolerance, and mortality in selected patients with COPD. The National Emphysema Treatment Trial (NETT) demonstrated that patients with severe, upper lobe predominant emphysema who have lung volume reduction surgery have significant benefits in health-related quality of life as well as exercise tolerance.[36] Subjects who also had persistently poor exercise tolerance before surgery appeared to have the most benefit compared with control subjects with similar impairment. These patients also had a mortality benefit.[36] The rationale for the surgery is that removing the areas of the lung most involved with emphysema can improve the physiology of the remaining lung. This includes improvement in expiratory airflow and improved lung elastic

recoil as well as improved ventilation–perfusion matching. The major patient selection criteria for lung volume reduction surgery are depicted in **Table 19-5**. After a successful surgery, patients can have improved gas exchange and may no longer require supplemental oxygen.

Table 19-5
Major Selection Criteria for Lung Volume Reduction Surgery

Moderate-to-severe airflow obstruction
Hyperinflation
Upper lobe predominant emphysema
Nonsmoker
Rehabilitation potential

The CXR for this patient suggests upper lobe predominant emphysema. This would need to be confirmed with a high-resolution computed tomography scan of the chest. Furthermore, the patient would need to complete a comprehensive pulmonary rehabilitation program before surgery. Only a few centers within the United States are certified by Medicare to perform lung volume reduction surgery, and this could be an important issue for P.J., depending on where he lives. It should be stressed that lung volume reduction surgery is only appropriate for a select group of patients with advanced emphysema.

In patients with severe emphysema, another option is lung transplantation. This intervention has been shown to improve quality of life and exercise tolerance in carefully selected candidates.[122] Bilateral lung transplantation may be associated with more prolonged survival compared to single lung transplantation in some patients, but further study is necessary.[123]

Acute and Chronic Rhinitis

Suzanne Bollmeier and Dennis M. Williams

CORE PRINCIPLES		CHAPTER CASES
1	Rhinitis is a common disorder and refers generally to inflammation in the nasal cavity. Common manifestations can include nasal discharge, itching, sneezing, congestion, and postnasal drip. Rhinitis can be caused by allergic, nonallergic, or mixed allergic and nonallergic triggers. Distinguishing the subtype can be helpful in targeting symptomatic treatment and prevention.	**Case 20-1 (Question 1)** **Case 20-8 (Question 2)** **Case 20-9 (Question 1)**
2	Oral antihistamines are the most common therapies used for treating allergic rhinitis. They are convenient and effective for most rhinitis symptoms including rhinorrhea, sneezing, and itching.	**Case 20-1 (Question 4)**
		Case 20-1 (Question

3	Second-generation antihistamines are preferred over first-generation agents based on a superior side-effect profile and convenience of dosing.	4)
4	Intranasal antihistamines offer an alternative to oral agents, with the advantage of efficacy for congestion and symptoms from some nonallergic causes. Side effects can challenge patient acceptance, however.	**Case 20-1 (Question 5)**
5	Intranasal corticosteroids are the most effective therapies available for treating a variety of rhinitis disorders. They are safe, well tolerated, and are highly effective in reducing itching, sneezing, rhinorrhea, and congestion.	**Case 20-3 (Question 3)**
6	Proper administration technique is important for intranasal therapies to maximize effectiveness and minimize the risk of side effects and toxicities.	**Case 20-1 (Question 5)** **Case 20-2 (Question 3)** **Case 20-3 (Question 7)**
7	Leukotriene modifiers are not recommended first line for treating patients with allergic rhinitis owing to cost and other products with superior efficacy. Leukotriene modifiers may be beneficial for select patient populations (eg, those with concomitant asthma or aspirin sensitivity).	**Case 20-4 (Question 2)**
8	The duration of use of topical decongestants should be limited to 3 to 5 days.	**Case 20-7 (Question 1)**

9	Ophthalmic therapies may be indicated if ocular itching, tearing, and redness are the primary symptoms or continue to be bothersome despite appropriate therapy for nasal symptoms associated with rhinitis.	**Case 20-1 (Question 5)**
10	Many patients seek complementary and alternative therapies to treat rhinitis conditions, despite limited evidence regarding their effectiveness.	**Case 20-5 (Question 1)**

INTRODUCTION

Rhinitis is defined as an inflammatory condition affecting the mucous membranes of the nose and upper respiratory system. In clinical practice, however, the term is used broadly to encompass a heterogeneous group of nasal disorders characterized by periods of rhinorrhea (nasal discharge), pruritus (itching), sneezing, congestion, and postnasal drainage (postnasal drip). These nasal symptoms can be accompanied by ocular symptoms such as redness, itching, and discharge and can be exacerbated by the development or presence of sinusitis. The most common form of rhinitis occurs in response to an allergen, although a variety of other subtypes have been demonstrated.[1–3]

CAUSES AND CLASSIFICATIONS

Rhinitis is not a single disease but rather has multiple causes and underlying pathophysiologic mechanisms with multiple phenotypes commonly divided into allergic, nonallergic, mixed, and infectious.[2–4] **Figure 20-1**[2,3] depicts common causes of acute and chronic rhinitis

symptoms, including some conditions that mimic rhinitis (eg, nasal polyps). The most common cause of acute rhinitis is a viral upper respiratory infection, that is, the common cold.

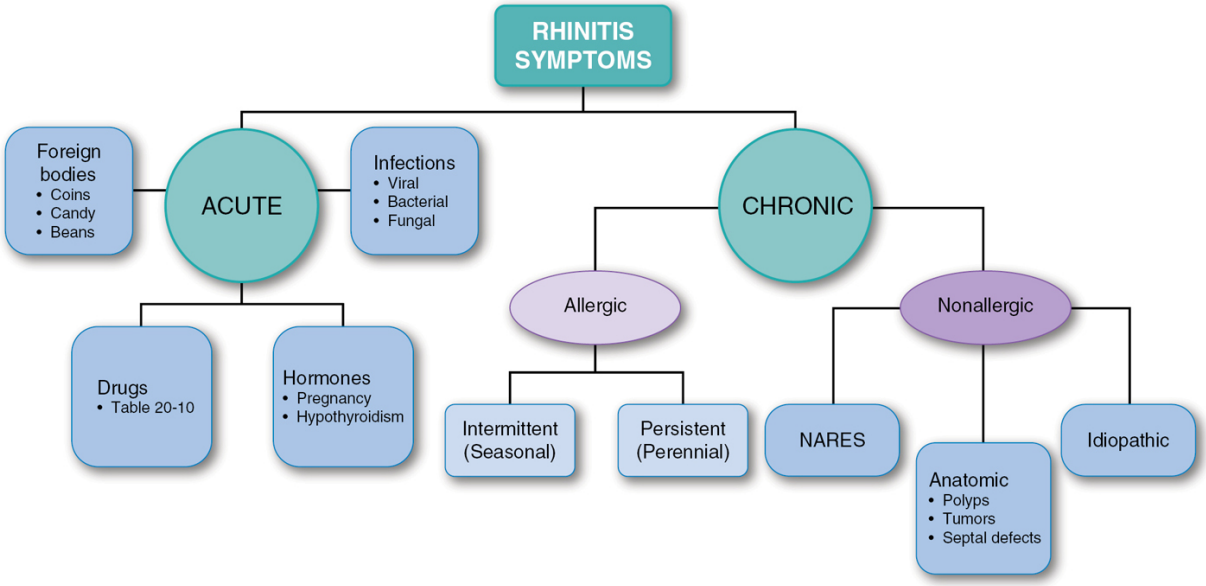

Figure 20-1 Possible causes of rhinitis symptoms. NARES, nonallergic rhinitis with eosinophilia syndrome.

In most patients, these viral infections are self-limited and require only symptomatic treatment. Nasal foreign bodies are another frequent cause and should be suspected when a pediatric patient presents with acute, unilateral symptoms.[3] Hormonal, food, and medication-related rhinitis are also common acute syndromes.[3,5]

Chronic rhinitis can be classified as allergic, nonallergic, or mixed allergic and nonallergic.[2] Allergic rhinitis, the most common subtype, is typically associated with atopy, an inherited tendency to develop a clinical hypersensitivity condition, and its symptoms are a result of immunoglobulin E (IgE)-dependent events.[5] There is not a single, uniform standard for classifying allergic rhinitis. In the past, patients were classified as having seasonal or perennial disease, based on the frequency of symptoms and potential offending allergens.[1] A newer approach categorizes allergic rhinitis based on severity (eg, mild or moderate to severe) and frequency (eg, intermittent or persistent) of symptoms.[1,6] This classification system is summarized

in **Figure 20-2**. Clinicians are likely to encounter a combination of these two classification schemes when evaluating clinical literature and participating in patient care activities. Product labeling from the Food and Drug Administration (FDA) utilizes both classification systems.

Intermittent[a] Disease	Persistent[b] Disease
Symptoms occur: Fewer than 4 days/week *or* for fewer than 4 weeks	**Symptoms occur:** At least 4 days/week *and* for at least 4 weeks
Mild	**Moderate–Severe**
All of the following:	At least *one* of the following:
• Normal sleep	• Impaired sleep
• No impairment of usual daily activities, sports, and leisure	• Impairment of daily activities, sports, and leisure
• No interference with work or school	• Interference at work or school
• No troublesome symptoms	• Troublesome symptoms

[a]Formerly "seasonal" symptoms.
[b]Formerly "perennial" symptoms.

Figure 20-2 ARIA classification of allergic rhinitis. ARIA, Allergic Rhinitis and its Impact on Asthma. (Source: Bousquet J, Khalteav N, Cruz AA, et al. Allergic rhinitis and its impact on asthma (ARIA) 2008 update (in collaboration with the World Health Organization, GA(2) LEN and AllerGen). *Allergy*. 2008;63(suppl 86):8–160. Reprinted by permission of John Wiley & Sons, Inc.)

Several categories exist for nonallergic causes of rhinitis, including drug-induced rhinitis, hormonal rhinitis (ie, pregnancy), nonallergic occupational rhinitis, idiopathic rhinitis,[7] and vasomotor rhinitis, which is the most common form.[8] Vasomotor rhinitis and nonallergic rhinitis are often used interchangeably. In vasomotor rhinitis, symptoms are often associated with environmental factors including temperature or barometric pressure changes, strong chemical odors,[8] tobacco smoke,[9] stress, or emotional factors.[10] Another form is nonallergic

rhinitis with eosinophilia syndrome (NARES) where patients have no evidence of allergic disease except the presence of >20% eosinophils in nasal smears.[11] Mixed rhinitis is a subset of allergic rhinitis in which features of both allergic and nonallergic diseases are present. These patients can be hard to differentiate but will have at least one nonallergic trigger such as temperature changes, tobacco smoke, perfumes, and cleaning products is present.[8] The presence of mixed disease should not be overlooked when evaluating the presentation of a patient or assessing the response to therapy.

EPIDEMIOLOGY AND IMPACT

Prevalence rates for rhinitis are difficult to quantify because the condition is often undiagnosed, different definitions are used, and data collection methods vary. A conservative estimate suggests that the prevalence of allergic rhinitis in the United States is ~7.7% of adults and 7.2% of children[12] (via physician diagnosis), but it may be as high as up to 30% in adults (and even more children), based on self-reported nasal symptoms,[2] making it the fifth most common chronic illness in the United States.[1] According to recent survey data, the number of children with respiratory allergies in the past 12 months was nearly 7 million, and adults reporting a diagnosis of hay fever in the past 12 months was 19.2 million.[12]

In recent decades, the prevalence in Western societies has increased, and studies from around the world are reporting similar trends.[5,13] Although studies have traditionally reported a 3:1 ratio of allergic to nonallergic rhinitis, recent data suggest that 35% to 50% of patients may experience symptoms from mixed causes.[8]

Rhinitis can lead to a worsening in sleep quality, cognitive function and mood, decreased work productivity, and a worsening of asthma or sinusitis. Also, patients with rhinitis are typically less attentive in school because of decreased concentration and difficulty learning.[14] Although many patients will self-treat their rhinitis symptoms, visits to provider offices are common.[15] A patient with allergic rhinitis will visit

the provider approximately three more times per year and fill nine more prescriptions yearly compared to a patient without rhinitis.[16]

Although rhinitis does not lead to the mortality associated with some illnesses, its prevalence and negative health impact make it an important health problem in the United States. Allergic diseases are a frequent contributor to health-related absenteeism.[17] It is estimated that 10.7 million workdays are missed because of allergic rhinitis in the United States per year.[17]

ANATOMY AND PHYSIOLOGY

The external nose is pyramidal and consists of paired nasal bones and associated cartilage. Its base has two elliptical-shaped openings called nares or nostrils. Internally, a septum divides the nasal cavity into two separate compartments and consists of bone and cartilage covered by a mucosal membrane.[18]

The membranes of the nasal cavity consist primarily of pseudostratified ciliated columnar epithelial cells with mucus-producing goblet cells interspersed among them.[19] The mucous lining serves as a protective shield against bacterial and viral infections.[19] The tiny cilia beat rhythmically to transport mucus across the upper airway membrane to the nasopharynx. In addition, respiratory secretions residing on these mucous membranes contain immunoglobulin A (IgA), which serves as an immunologic defense.[19]

The autonomic nervous system controls the vascular supply and the secretion of mucus to the nasal membrane. Sympathetic activation results in vasoconstriction, which decreases nasal airway resistance.[19] Parasympathetic stimulation results in glandular secretion and nasal congestion.[19] The mucosa is also innervated by the nonadrenergic–noncholinergic system. Neuropeptides from these nerves (eg, substance P and neurokinins) play a role in vasodilation, mucus production, and inflammation,[19] although their significance is unclear. The trigeminal nerve also provides sensory innervation.[19] The primary functions of the nose and upper airway

are smell, speech, and the exchange of air between the internal and external environments.[19] These processes are disrupted in the presence of inflammation, increased mucus, and congestion.

ETIOLOGY OF ALLERGIC RHINITIS

Genetic, environmental, and lifestyle influences are associated with the development of allergic rhinitis.[20] Candidate genes have not been identified[20]; however, atopy is a significant inheritable factor, and the risk of a child experiencing allergic symptoms is ~44% to 50% with one atopic parent[2,5] and is even more likely with two atopic parents.[5] Environmental exposures, particularly early in life, are also important in the development of symptoms.[21] In addition, lower socioeconomic status may be a risk factor for the development of allergic rhinitis.[21]

One etiologic theory, referred to as the hygiene hypothesis, suggests that the initial differentiation of lymphocytes early in life has either positive or negative influences on the development of subsequent allergies. In the normal development of the immune system, the lymphocytes differentiate into helper T (either T_H1 or T_H2) cells based on environmental stimuli. Factors associated with a T_H1 (allergy protective) response include exposures to various bacteria and viruses, the presence of older siblings, and early attendance in daycare. Factors associated with a T_H2 (predisposition to allergies) response include environmental exposures to house dust mites, cockroaches, or early, frequent antimicrobial use.[4,5]

Aeroallergens are common triggers for allergic rhinitis and are grouped into indoor, outdoor, or occupational agents. Indoor allergens include dust mites, pet dander, and insects. Outdoor allergens are pollens and mold, which create a greater risk of intermittent or seasonal symptoms as seasonal peaks and abundance in certain hot and humid areas increase their development.[22] It is postulated that global warming and climate

change also impact seasonal allergic rhinitis. Ragweed season, for example, is starting earlier and ending later in the central Midwest United States.[23] Interestingly, ragweed is intolerant to frost.[24]

PATHOPHYSIOLOGY

Allergic rhinitis is characterized by an IgE-mediated response that involves three primary steps: sensitization, early-phase events, and late-phase events.[4,25] This process is depicted in **Figure 20-3**. The nonallergic pathogenic course is less well understood. It is not IgE-mediated, although in some subtypes inflammatory cells and mediators can cause similar effects to those seen in the allergic form.[25]

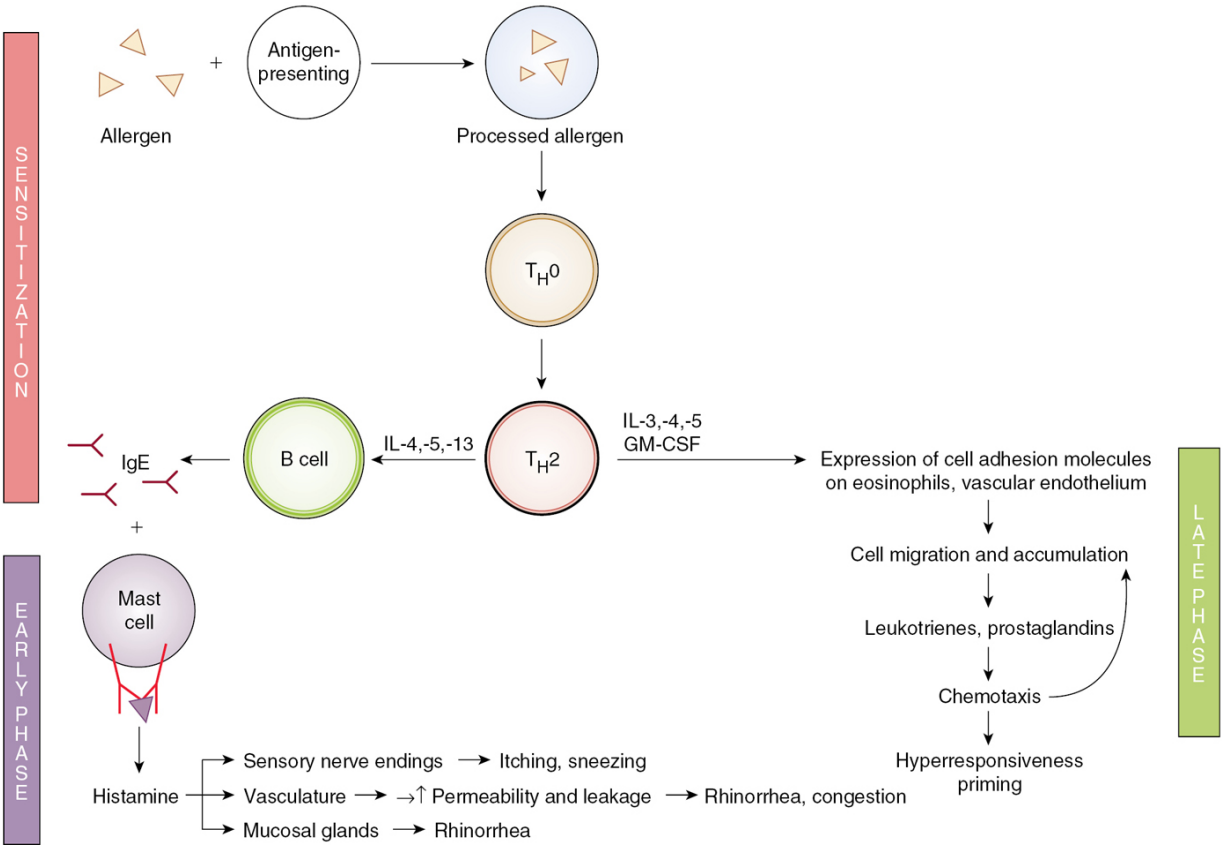

Figure 20-3 Pathophysiology of allergic rhinitis. GM-CSF, Granulocyte macrophage –colony stimulating factor; IL, interleukin.

Sensitization

In atopic patients, sensitization to an allergen occurs after initial exposure causing the production of IgE antibodies. These antibodies bind to receptors on mast cells. Upon subsequent exposure, activation of an inflammatory response is initiated because of the cross-linking of the allergen, IgE antibody, and the mast cell.[5]

Early Response

After initial exposure, antigen-presenting cells of the immune system react to allergens deposited on the nasal mucosa.[5] Mast cells and other cells, such as basophils,[26] then release both new and preformed chemotactic[26] inflammatory mediators, such as histamine, which can cause localized inflammation.[4] Symptoms associated with this early response can occur within minutes, including sneezing, rhinorrhea, and nasal itching.[5] Histamine receptors (H_1) are present throughout the nasal mucosa and airway. Their activation results in vascular engorgement, leading to nasal congestion and rhinorrhea.[26] In addition, histamine stimulates sensory nerves of the parasympathetic nervous system in the upper airway causing other inflammatory mediators such as basophils,[5] eosinophils, lymphocytes, macrophages, and dendritic cells to migrate to the upper airway, contributing to a late-phase response.[26]

Late Response

Up to one-third of patients with allergic rhinitis also experience a late response that develops ~4 hours after initial exposure and may persist for up to 8 hours.[27] In this phase, the nature of inflammation is even more complex, and nasal congestion is a prominent feature.[27] Numerous cells and mediators, including T_H2 lymphocytes, cytokines, basophils, eosinophils, neutrophils, macrophages, and leukotrienes, play important roles.[4] These additional mediators, attracted to the area through chemotaxis, sustain the inflammatory

response.[4] Also, some chemotactic proteins can cause damage to the airway epithelium and expose local nerve fibers.[4] Continued exposure to the offending allergen can also prolong the late-phase reaction.

CLINICAL PRESENTATION AND ASSESSMENT OF RHINITIS

The diagnosis of rhinitis is not defined by one specific laboratory test; rather, it is related to the coordinated results of a thorough patient interview, including medication history, pertinent physical examination, and a limited number of relevant laboratory assessments.

Risk Factors

Several elements increase the risk of developing allergic rhinitis. Atopy, parental history, introduction of formula in infancy, exposure to maternal smoking at age younger than 1 year, serum IgE levels >100 IU/mL before age 6 years, ethnic origin other than White European, environmental pollution, birth during pollen season, no older siblings, late entry into nursery or preschool, and exposure to indoor allergens such as animal dander and dust mites as well as concomitant food allergies[26] are risk factors.[5]

History, Signs, and Symptoms

A history should be obtained from the patient that includes details of the onset (including seasonality),[3] character, frequency, duration, and severity of the patient's symptoms and any identifiable factors that provoke or relieve these symptoms.[5] Past medical history (including the age of onset of symptoms) and family history (eg, atopy) are also helpful.[5] Other symptoms such as sleep problems,

snoring, repeated sniffing, and allergic salute and shiner should also be noted.[3]

Both allergic and nonallergic forms of rhinitis are common and can potentially coexist.[2] Diagnostic criteria suggestive of allergic rhinitis include nasal discharge, itching, sneezing, and nasal congestion.[3] Occasionally, patients will present with a decreased sense of smell.[5] Symptoms of allergic conjunctivitis include itchy, watery eyes,[5] which occur in ~50% to 70% of patients with allergic rhinitis. Their presence can be used to differentiate allergic rhinitis from other forms.[5] Persistent congestion and/or rhinorrhea[25] like changes in temperature, air conditioning, pollutants, tobacco smoke, and other irritants suggest that nonallergic triggers may be involved. The negative impact of rhinitis on a patient's quality of life can be substantial, and it is important to assess this during the patient interview. Symptoms and symptom-induced interference with necessary (ie, work, school) and enjoyable (eg, hobbies, family events) activities can lead to patient anger, sadness, irritation, and withdrawal.[5] The questions listed in **Figure 20-4** provide a guide to collecting the information needed to initiate and modify therapy based on the underlying causes of the rhinitis symptoms.

1. Which of the common symptoms of rhinitis is the patient experiencing?
   - Sneezing, nasal itching, runny nose, nasal congestion, postnasal drip, altered sense of smell, watery eyes, itching eyes, ear “popping”

2. What color are the nasal secretions?
   - Clear, white, yellow, green, blood-streaked, rusty brown

3. When did the symptoms first appear?
   - Infancy, childhood, adulthood

4. Were the symptoms associated with a change in state/environment?
   - After a viral upper respiratory infection, after a traumatic blow to the head or face, upon moving into/visiting a new dwelling, after obtaining a new pet

5. How often do the symptoms occur?
   - Daily, episodically, seasonally, constantly

6. For how long has this symptom pattern persisted?
   - Days, weeks, months, years

7. Which factors or conditions precipitate symptoms?
   - Specific allergens, inhaled irritants, climatic conditions, food, drinks

8. Which specific activities precipitate symptoms?
   - Dusting, vacuuming, mowing grass, raking leaves

9. Are other members of the family experiencing similar symptoms?

10. Which of the following are prevalent in the household?
    - Carpeting, heavy drapes, foam or feather pillows, stuffed toys, areas of high moisture (basements, bathrooms), tobacco use (by patient or others), pets

11. Does the patient have other medical conditions that can cause similar symptoms?

12. Is the patient taking any medications that might cause or aggravate these symptoms?

13. What prescription and nonprescription medications have been used for these symptoms in the past? Were they effective? Did they cause any unwanted effects?

14. What is the patient's occupation?

15. What are the patient's typical leisure activities?

16. To what extent have the symptoms interfered with the patient's lifestyle (ie, are they disabling or merely annoying)?
    - Greatly, somewhat, not much

Figure 20-4 Patient history interview.

Diagnosis

PHYSICAL EXAMINATION

During a physical examination for rhinitis, the patient's nose should be inspected for the position of the septum, appearance of the nasal mucosa, secretions, and any growths.[3] Common physical characteristics of patients with allergic rhinitis are clear nasal discharge, swollen nasal membranes,[4] allergic shiners (discoloration under the lower eyelids owing to vasodilation or venous congestion), and allergic salute (horizontal nasal crease across the bridge of the nose as a result of repeated upward rubbing of the tip of the nose by the palm).[8] The patient's eyes, ears, throat, lung, and skin should also be examined.[8] Chronic mouth breathing because of nasal obstruction can cause recognizable facial characteristics (eg, adenoid face and dental abnormalities).[1] Many patients with chronic rhinitis will have a decreased sense of smell or taste and may also experience ear popping and pressure owing to auditory tube dysfunction.[8]

Laboratory Tests

Several diagnostic tests are available for confirming a diagnosis of allergic rhinitis in patients who present with a suggestive history and symptoms. Microscopic examination of nasal secretions can be performed, but consensus on their usefulness is lacking.[1] In allergic conditions, the clinician would expect numerous eosinophils to be present in the sample; however, this could also be true of NARES or nasal polyps.[28]

Immediate hypersensitivity skin tests are used to demonstrate an IgE-mediated response of the skin to an allergen.[1] A variety of skin test methods are available; however, the skin-prick/puncture technique (in which the wheal-and-flare reaction is evaluated 15–20 minutes after allergen administration) is preferred.[1] A primary point of differentiation between pure allergic versus nonallergic disease is the presence of a serum IgE level >100 international units/mL

(especially before age 6), which is consistent with atopy.[5] However, a clinical diagnosis of either allergic or nonallergic disease is often made in the absence of a serum IgE and is based on the nature of symptoms and triggers.

OVERVIEW OF TREATMENT

There are two primary guideline resources available that summarize the evidence and expert opinion regarding the diagnosis and management of allergic rhinitis. The first, from the American Academy of Otolaryngology, Head and Neck Surgery Foundation, was published in early 2015 by a panel consisting of 20 members representing experts in the field of allergy and immunology.[1] The British Society of Allergy and Clinical Immunology has also developed a revised guideline for the diagnosis and management of both allergic and nonallergic rhinitis that was last updated in 2017.[3] In addition, evidence linking asthma and allergic rhinitis epidemiologically, pathologically, and physiologically has been published, suggesting that upper respiratory allergic disorders and asthma represent components of a single inflammatory airway syndrome.[4] This prompted the development and subsequent updates of the Allergic Rhinitis and its Impact on Asthma (ARIA) guidelines most recently in 2010 and a brief update was published in 2017, which provide direction for clinicians caring for patients with both conditions.[6] The 2010 document includes information about the use of complementary and alternative therapies, rhinitis in athletes, and grading the evidence used to establish the guidelines.[29] Guidelines for the treatment of seasonal allergic rhinitis were published in 2017 by the Joint Council of AAAAI and ACAAI and are evidence based.[30]

The treatment goals for rhinitis are to prevent or relieve symptoms and improve quality of life without adverse drug effects or excessive cost. These goals should be achievable through the establishment of a therapeutic partnership with a competent and caring clinician. With

appropriate treatment, the patient should be able to maintain a normal lifestyle and perform desired activities. Common management strategies include patient education, allergen and irritant avoidance, and pharmacotherapy.[1,3,4,26] **Figures 20-5** and **20-6** depict algorithms for the general management of intermittent and persistent allergic rhinitis.

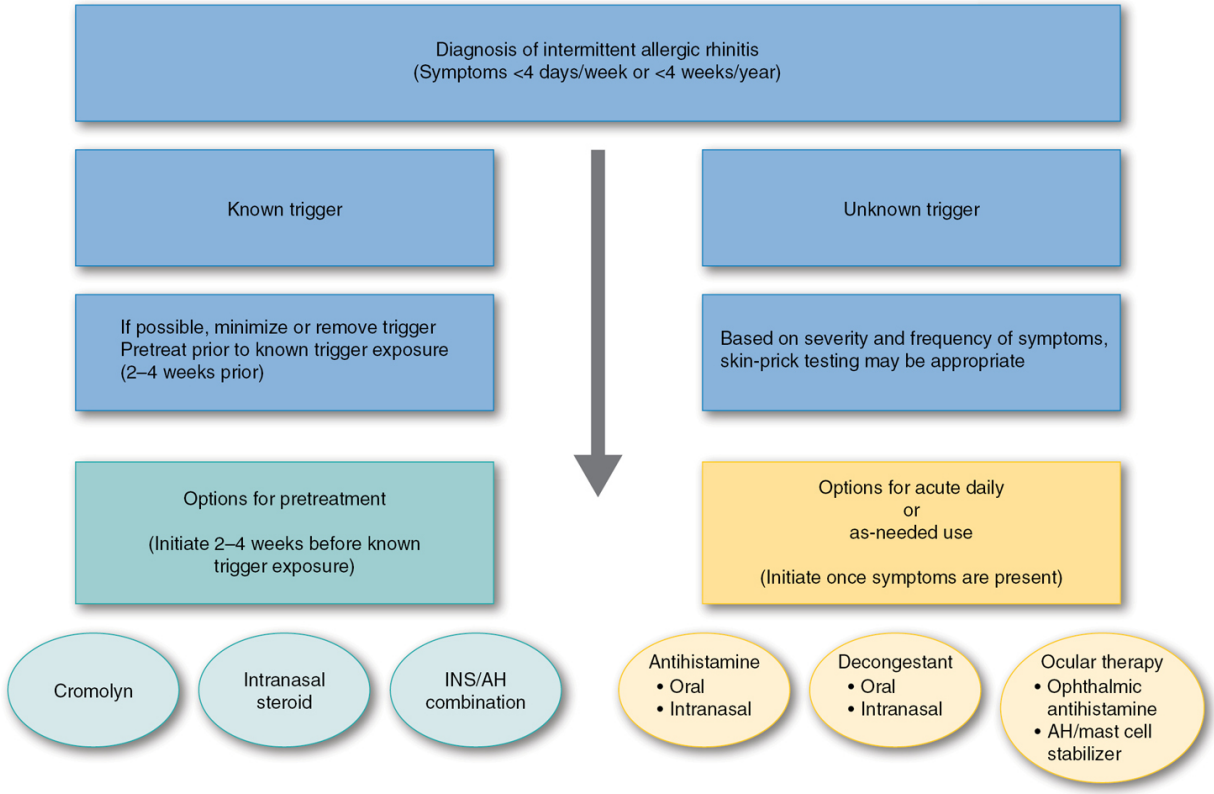

Figure 20-5 Treatment algorithm for persistent allergic rhinitis. Treatment should be directed at predominant symptoms (eg, for eye symptoms in the absence of other symptoms use ophthalmic preparation). Prevention strategies are just as important and effective as treatment strategies. INS/AH, intranasal steroid/intranasal antihistamine combination. (From Brozek JL, Bousquet J, Agache I, et al. Allergic Rhinitis and its Impact on Asthma (ARIA) guidelines-2016 revision. *J Allergy Clin Immunol.* 2017;140(4):950–958; Seidman MD, Gurgel RK, Lin SY, et al. Clinical practice guideline: allergic rhinitis. *Otolaryngol Head Neck Surg.* 2015;152(1S):S1–S43; Scadding GK, Kriyawasan HH, Scadding G, et al. BSACI guideline for the diagnosis and

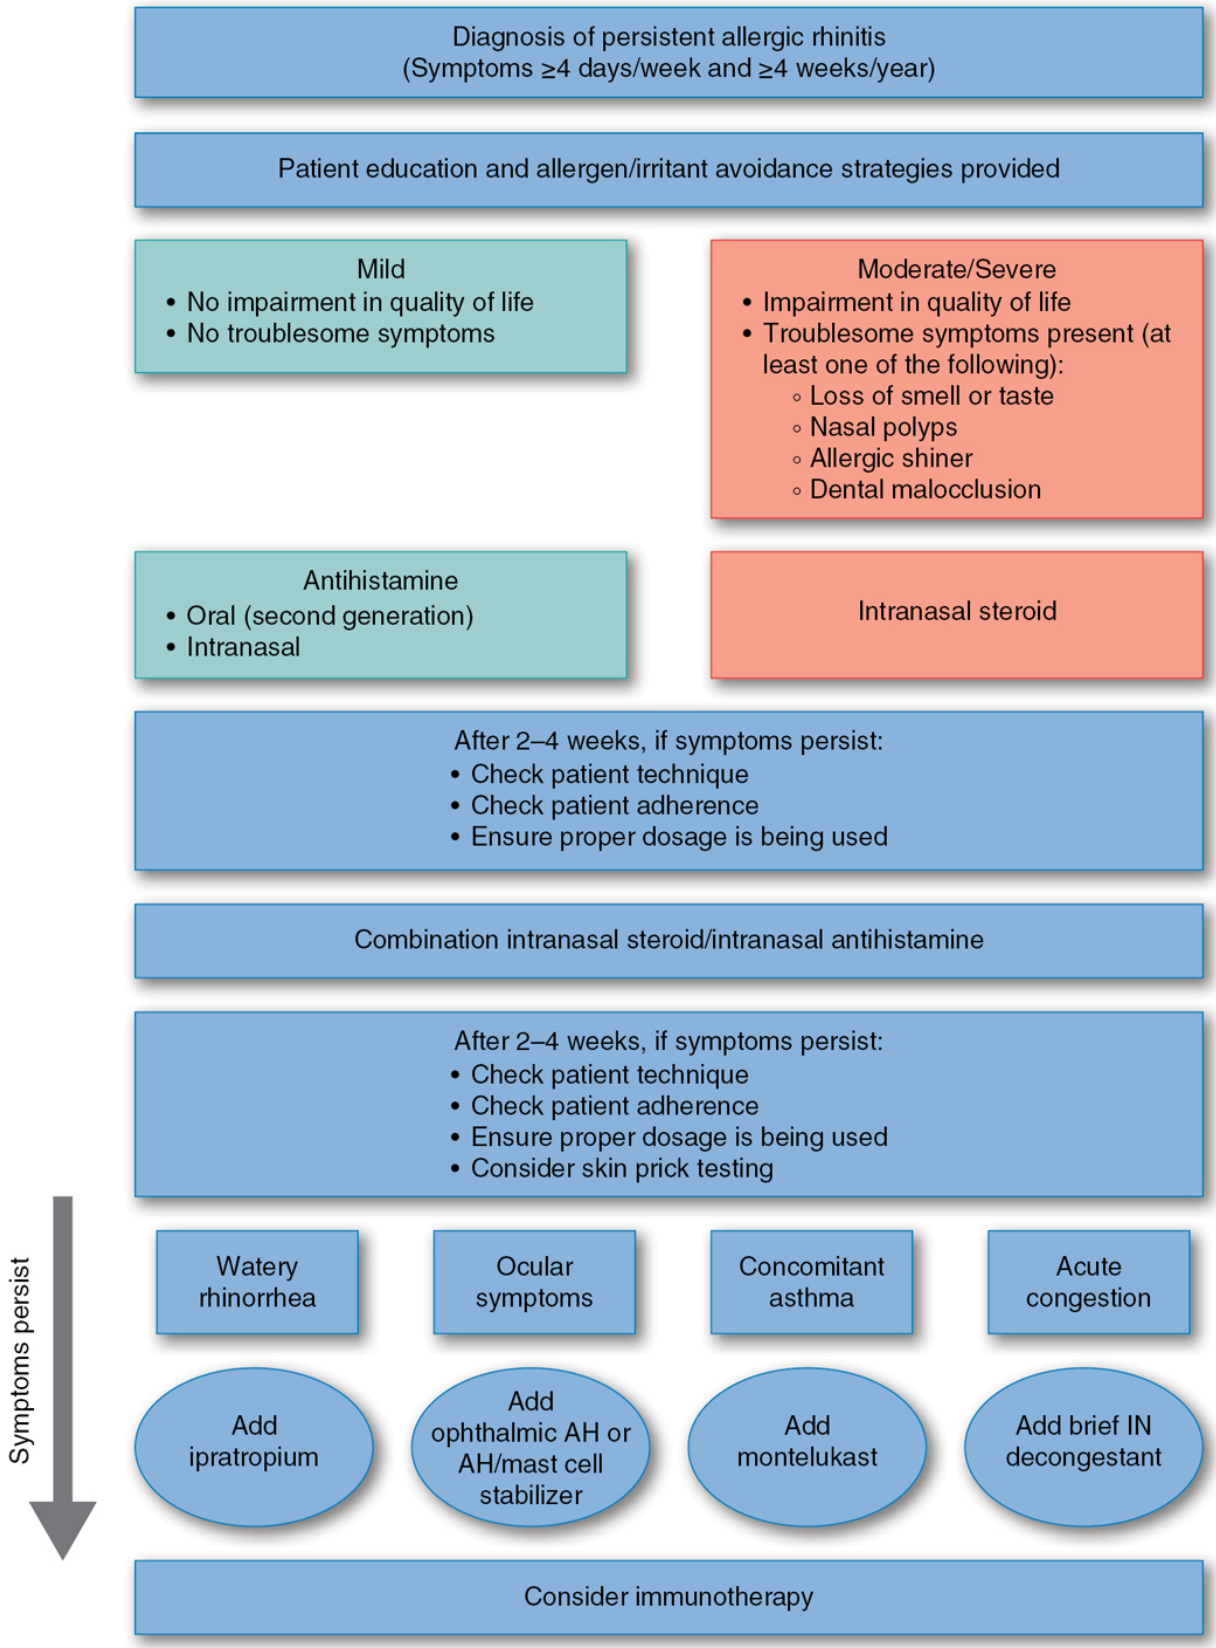
management of allergic and non-allergic rhinitis (Revised edition 2017: First edition 2007). *Clin Exp Allergy.* 2017;47:856–889.)



Diagnosis of persistent allergic rhinitis
(Symptoms ≥4 days/week and ≥4 weeks/year)
Patient education and allergen/irritant avoidance strategies provided
Mild
• No impairment in quality of life
• No troublesome symptoms
Moderate/Severe
• Impairment in quality of life
• Troublesome symptoms present (at least one of the following):
◦ Loss of smell or taste
◦ Nasal polyps
◦ Allergic shiner
◦ Dental malocclusion
Antihistamine
• Oral (second generation)
• Intranasal
Intranasal steroid
After 2–4 weeks, if symptoms persist:
• Check patient technique
• Check patient adherence
• Ensure proper dosage is being used
Combination intranasal steroid/intranasal antihistamine
After 2–4 weeks, if symptoms persist:
• Check patient technique
• Check patient adherence
• Ensure proper dosage is being used
• Consider skin prick testing
Symptoms persist
Watery rhinorrhea
Ocular symptoms
Concomitant asthma
Acute congestion
Add ipratropium
Add ophthalmic AH or AH/mast cell stabilizer
Add montelukast
Add brief IN decongestant
Consider immunotherapy

Figure 20-6 Treatment algorithm for intermittent allergic rhinitis. antihistamine; INS, intranasal steroid. (From Wallace DV, Dykewicz MS, Oppenheimer J, Portnoy J, Lang DM. Pharmacologic treatment of seasonal allergic rhinitis: Synopsis of guidance from the 2017 Joint Task Force on Practice Parameters. *Ann Intern Med.* 2017;167:876–881.)

Patient Education

Patients should be educated about their rhinitis. Considerations for patient education include instruction about the disease and specific triggers, the range of symptoms, the role of various treatments, and suitable technique for nasal drug delivery.[5] A discussion of allergen and trigger avoidance is also important.

Allergen and Irritant Avoidance

Although the benefit of allergen avoidance has proved difficult to document, this strategy is considered central in a comprehensive management plan for allergic rhinitis.[1,5,9,26] Various strategies for minimizing exposure to known allergens (eg, pollens, house dust mites, molds, animal dander, and cockroaches) are commonly used for prevention. Because little evidence supports a single physical or chemical intervention to reduce allergen exposure, a multifaceted approach should be used.[1] Efforts to reduce exposure to irritants (eg, tobacco smoke, indoor, or outdoor pollutants) should also be recommended because it is anticipated that this would have similar benefits as allergen avoidance.[3]

Pharmacotherapy

Several classes of medications are used in the management of rhinitis disorders. Choices should be based on goals of treatment, safety, efficacy, cost-effectiveness, adherence, severity, comorbidity, and patient preferences. Common therapies are administered either

orally or topically and used on a regular schedule or on an as-needed basis.[1] Few cost-effectiveness data exist comparing the classes of therapy, except the second-generation antihistamines (SGAs),[31] nasal corticosteroids,[32] and subcutaneous immunotherapy,[33] which are cost-effective. **Table 20-1** summarizes the effectiveness of agents for specific symptoms used in the treatment of allergic rhinitis.

Table 20-1
Effectiveness of Agents[a] Used in the Management of Allergic Rhinitis

	Rhinorrhea	Nasal Pruritus	Sneezing	Nasal Congestion	Eye Symptoms	Onset
Antihistamines						
Nasal	Moderate	High	High	Moderate	0	Rapid
Ophthalmic	0	0	0	0	Moderate	Rapid
Oral	Moderate	High	High	0/Low	Low	Rapid
Decongestants						
Nasal	0	0	0	High	0	Rapid
Ophthalmic	0	0	0	0	Moderate	Rapid
Oral	0	0	0	High	0	Rapid
Corticosteroids						
Nasal	High	High	High	High	High	Slow (days)
Ophthalmic	0	0	0	0	High	Slow (days)
Mast-Cell Stabilizers						
Nasal	Low	Low	Low	0/Low	Low	Slow (weeks)
Ophthalmic	Low	Low	Low	Low	Moderate	Slow (weeks)
Anticholinergics						
Nasal	High	0	0	0	0	Rapid
Leukotriene Modifiers						
Oral	Low	0/Low	Low	Moderate	Low	Rapid

High, significant effect; moderate, moderate effect; low, low effect; 0, no effect.

[a]Immunotherapy can lead to significant responses in all symptom categories; however, the onset of action is delayed (months).

ANTIHISTAMINES

Antihistamines are the most common treatment for allergic rhinitis and are effective for relieving sneezing, itching, and rhinorrhea. They also diminish eye symptoms but, when taken orally, have minimal effects on nasal congestion.[2,3] Although first-generation antihistamines (FGAs) are efficacious, their use is limited by anticholinergic, sedative, and performance-impairing effects, which challenge their cost-effectiveness.[9] As a result, SGAs are preferred over FGAs in most cases where an antihistamine is desired.[1] Antihistamines are available in oral, ophthalmic, and intranasal formulations and can also be found in combinations with oral decongestants. They are most effective when administered before allergen exposure.

Although oral antihistamines (**Table 20-2**) represent the most commonly used therapy for allergic rhinitis, there is evidence that intranasal antihistamines are equal or superior in efficacy to oral agents. Further, they appear to relieve symptoms of mild congestion, which is not a feature of oral antihistamines.[1] Intranasal antihistamines work quickly, within 15 to 30 minutes, but may be complicated by a bitter taste.[1] The improved efficacy of intranasal antihistamines over oral agents in certain rhinitis conditions may be because of direct administration to the affected site. Olopatadine 0.6% is FDA approved for treating seasonal allergic rhinitis in patients age older than 6 years.[1] Azelastine 0.1% and 0.15% are FDA approved for treating both intermittent (0.1% age older than 6 months to age younger than 6 years) and persistent allergic rhinitis (0.15% in those age older than 6 years).[34]

Table 20-2
Oral Antihistamines[a,b] Commonly Used in Allergic Rhinitis

Generic Name (Example Brand Product)	Adult Dose	Pediatric Dose[c]	Other Effects		
First generation			Sedative	Antiemetic	Anticholinergic
Chlorpheniramine (Chlor-Trimeton®)	4 mg every 4–6 hours	Children 6–12 years: 2 mg every 4–6 hours Children 2–6 years: 1 mg every 4–6 hours	+	0	++
Clemastine (Tavist®)	1 mg every 12 hours	Children 6–11 years: 0.67 mg every 12 hours	++	++	+++
Diphenhydramine (Benadryl®)	25–50 mg every 4–8 hours	Infants and children 12.5–25 mg every 6-8 hours Adolescents: 25-50 mg every 6-8 hours	+++	++	+++
Second generation			Sedative	Antiemetic	Anticholinergic
Cetirizine (Zyrtec Allergy®)	5–10 mg once daily	Children ≥6 years: 5–10 mg once daily Children 2–5 years: 2.5 mg once daily, 2.5 mg twice daily, or 5 mg once daily Children 6–11 months: 2.5 mg once daily Children 12–23 months: 2.5 mg once daily (max 5 mg daily)	+	0	±
Fexofenadine (Allegra®)	60 mg every 12 hours or 180 mg once daily	Children 2 to ≤12 years: 30 mg every 12 hours	±	0	±
Loratadine (Claritin®)	10 mg once daily	Children ≥6 years: 10 mg once daily or 5 mg twice daily Children ≥2 to ≤6 years: 5 mg once daily	±	0	±
Levocetirizine (Xyzal®)	5 mg once daily in the evening	Children 6–11 years: 2.5 mg once daily in the evening Children 6 months–5 years: 1.25 mg once daily in the evening	±	0	±
Desloratadine (Clarinex®)	5 mg once daily	Children 6–11 years: 2.5 mg once daily Children 1–5 years: 1.25 mg once daily Children 6–11 months: 1 mg once daily	±	0	±

[a]Many oral antihistamines are sold as combination products with the oral decongestants pseudoephedrine and phenylephrine. The addition of the decongestant may alter the dosing scheme for the product. As of 2005, pseudoephedrine products have been placed behind the pharmacy counter in the United States. Federal law limits the quantity available for purchase and requires a signature and photo identification. Individual states may have additional restrictions regarding the sale of pseudoephedrine. Consult local boards of pharmacy for details.

[b]Some oral antihistamines are available in both short-acting and extended- or sustained-release formulations. Refer to package insert for specific dosing instructions for long-acting products.

[c]In 2008, the Food and Drug Administration (FDA) issued an advisory alert recommending that over-the-counter (OTC) cough and cold agents (eg, products containing antitussives, expectorants, decongestants, and antihistamines) not be used in infants and children age younger than 2 years because of the potential for serious and possibly life-threatening adverse events (https://www.fda.gov/consumers/consumer-updates/should-you-give-kids-medicine-coughs-and-colds). More recently, in October 2008, leading pharmaceutical manufacturers voluntarily modified product labels on OTC cough

and cold preparations to state “do not use” in children age younger than 4 years (https://www.fda.gov/consumers/consumer-updates/should-you-give-kids-medicine-coughs-and-colds). Furthermore, in 2011, the FDA removed unapproved prescription allergy products from the market because they had not been proven to meet standards for safety, effectiveness, and quality (https://www.duanemorris.com/alerts/FDA_removes_unapproved_prescription_cough_cold_allergy_drugs_initiative_3985.html).

INTRANASAL CORTICOSTEROID AGENTS

Intranasal corticosteroids are the most effective medication class for the treatment of allergic rhinitis and are particularly useful for more severe or persistent symptoms.[1,3] Although achieving optimal outcomes depends on the patient’s ability to use the device correctly, if administered as intended, these agents are appropriate for all symptoms, are generally well tolerated, and have few adverse effects.[29] They are most beneficial when dosed on a regular schedule; some evidence indicates, however, that they are effective when used on an as-needed basis.[1,9] Intranasal corticosteroids are also useful for treating nonallergic rhinitis[28] and several are available over the counter (OTC).

LEUKOTRIENE MODIFIERS

Leukotriene modifiers are effective in relieving many of the nasal symptoms of allergic rhinitis such as daytime congestion, rhinorrhea, pruritis, sneezing, and improving sleep as well as congestion on awakening.[4] Current guidelines recommend against utilizing this class of drugs as first line.[1] They may have a role as an alternative option for preschool-aged children[30] with seasonal allergic rhinitis but are not recommended for adult patients with perennial allergic rhinitis.[29] In addition, selected patients might benefit from the combination of an antihistamine and a leukotriene modifier,[26] such as those with concomitant asthma and allergic rhinitis.[1,35] There is no evidence that these agents are helpful for symptoms from nonallergic causes.

CROMOLYN

Intranasal cromolyn, a nonsteroidal agent, acts as a mast-cell stabilizer and, although safe, it is generally less efficacious than other therapies and only useful for symptoms related to allergic causes. It should be administered multiple times daily and requires several weeks to be effective.[5] It is best reserved for prophylaxis before exposure to a known allergen[26,35] and, because of its excellent safety profile,[35] for use by children or in pregnancy.[34]

DECONGESTANTS

Oral and nasal decongestants (**Table 20-3**) can effectively reduce nasal congestion by activation of α-adrenergic receptors.[35] Oral agents are often combined with antihistamines and are generally well tolerated, but their use can lead to insomnia, nervousness, urinary retention, hypertension, and even palpitations that may be problematic for some patients.[36] Subsequently, these agents should be used with caution in elderly patients and in those with hyperthyroidism, cardiovascular disease, diabetes, glaucoma, or those who are pregnant.[36] Nasal agents are not typically associated with these effects but should be limited to short-term use to avoid rebound nasal congestion.[35] Because pseudoephedrine is used in the illegal manufacture of methamphetamine, there are now restrictions on the sale of nonprescription formulations.[36] Also, questions regarding the efficacy of phenylephrine[36] have resulted in challenges to the optimal use of oral decongestants.

Table 20-3

Decongestants[a,b] Commonly Used in Allergic Rhinitis

Generic Name (Example Brand Product)	Adult Dose	Pediatric Dose[c]
Oral[a]		
Pseudoephedrine (Sudafed®)	60 mg every 4–6 hours (max 240 mg/day) 120 mg SR every 12 hours 240 mg CR every 24 hours	Children 6–12 years: 30 mg every 4–6 hours (max 120 mg/day)

		Children 2–5 years: 15 mg every 4–6 hours (max 60 mg/day)
Phenylephrine (Sudafed PE®)	10 mg every 4 hours (max 60 mg/day)	Children ≥12 years of age and adolescents: 10 mg every 4 hours (max 60 mg/day) Children 6–11 years: 5 mg every 4 hours (max 30 mg/day) Children 4–5 years: 2.5 mg every 4 hours (max 15mg/day)
Topical[d]		
Phenylephrine (Neo-Synephrine®)	0.25%–1.0% solution: 2–3 sprays or drops/nostril not more than every 4 hours for not more than 3 days.	Children 6–11 years: 2–3 sprays or drops (0.25% solution)/ nostril not more than every 4 hours for not more than 3 days. Children 2–5 years: 2–3 drops (0.125% solution) into each nostril not more than every 4 hours for not more than 3 days.
Oxymetazoline (Afrin®)	0.05% solution: 2–3 sprays/nostril every 12 hours	Children 6–12 years: 2–3 sprays/nostril every 12 hours

CR, Controlled release; SR, sustained release.

[a]Many oral decongestants are sold as combination products with oral antihistamines. The addition of the antihistamine may alter the dosing scheme for the product. As of 2005, pseudoephedrine products have been placed behind the pharmacy counter in the United States. Federal law limits the quantity available for purchase to 9 g/month, 3.6 g/day with signature and photo identification. Individual states may have additional restrictions regarding the sale of pseudoephedrine. Consult local boards of pharmacy for details.

[b]Some oral decongestants are available in both short-acting and extended- or sustained-release formulations. Refer to package insert for specific dosing instructions for long-acting products. Note that some extended-release formulations are not recommended for children age younger than 12 years.

[c]In 2008, the FDA issued an advisory alert recommending that over-the-counter (OTC) cough and cold agents (eg, products containing antitussives, expectorants, decongestants, and antihistamines) not be used in infants and children age

younger than 2 years because of the potential for serious and possibly life-threatening adverse events (https://www.fda.gov/consumers/consumer-updates/should-you-give-kids-medicine-coughs-and-colds). More recently, in October 2008, leading pharmaceutical manufacturers voluntarily modified product labels on OTC cough and cold preparations to state “do not use” in children age younger than 4 years. Furthermore, in 2011, the FDA removed unapproved prescription allergy products from the market because they had not been proven to meet standards for safety, effectiveness, and quality.

[d]Limit duration of treatment to 5 days to minimize the risk of rebound congestion. Topical decongestants should never be used in preschoolers[24] or infants because of possible toxicity.[14]

ANTICHOLINERGIC AGENTS

Intranasal ipratropium bromide is an anticholinergic agent effective in reducing watery, nasal secretions in allergic rhinitis, nonallergic rhinitis, and viral upper respiratory infections.[35] Anticholinergic agents have no significant effects on other symptoms.

OPHTHALMIC THERAPIES

Ophthalmic products used to treat symptoms of allergic conjunctivitis include antihistamines, decongestants, mast-cell stabilizers, and nonsteroidal anti-inflammatory agents. These agents are effective in reducing ocular symptoms and may be used in combination with oral and intranasal agents.

IMMUNOTHERAPY

Specific allergen immunotherapy (SIT) should be considered for patients with IgE-mediated disease,[3] who have severe symptoms despite optimal pharmacotherapy,[2,5] those who experience side effects from drugs restricting their treatment choices,[5] or those who cannot avoid allergen exposure.[3] The clinical efficacy of immunotherapy by subcutaneous injection (SCIT), sometimes called “allergy shots,” is well established[2] and is the only treatment that can offer the potential for disease remission.[1–3] Traditional SCIT presents some disadvantages, such as cost, adherence, and rare adverse

systemic reactions.[1,37] More recently, the efficacy of immunotherapy given sublingually (SLIT) has been documented and the tablet form received FDA approval in April 2014.[1,38] See **Table 20-4** for details. There are potential adverse effects including local reactions such as oral itching[1] and swelling of the lips and mouth.[39] Systemic reactions can occur from both SCIT and SLIT and include urticaria, gastrointestinal upset, wheezing, and anaphylaxis.[1] Because of the potential for these reactions, SCIT is to be administered in the provider's office; however, after the first dose of SLIT, it may be given at home (on a daily basis).[2] Providers are urged to prescribe and educate patients on how to use injectable epinephrine for emergency use, and SLIT should not be given to patients with uncontrolled asthma or those on β-blocking agents.[34]

Table 20-4
Sublingual Tablet Immunotherapy

Drug Name	Allergen	Ages Approved for (in years)	Dosing	Dosing Considerations
Ragwitek®	Ragweed pollen	≥5–65	1 tablet SL once daily	Initiate treatment at least 12 weeks before the expected onset of each ragweed pollen season and continue throughout the pollen season.
Oralair®	Mixed grasses: sweet vernal, orchard, perennial rye, Timothy and Kentucky bluegrass	5–65	Adults: 300 IR SL once daily 5–17 years of age: 100 IR SL on day 1, then 200 IR on day 2, and then 300 IR once daily thereafter Remove sublingual tablet from blister immediately prior to administration	Initiate treatment 4 months before the expected onset of each grass pollen season and continue throughout the pollen season.
Grastek®	Timothy grass	5–65	5 and older: 2800 BAU SL once daily Remove sublingual tablet from blister immediately prior to administration	Initiate treatment at least 12 weeks before the expected onset of each grass pollen season and continue throughout the pollen season. May be taken daily for 3 consecutive years (including intervals between grass pollen seasons) In clinical trials, treatment interruptions of up to 7 days were allowed.
Odactra®	House dust mites	18–65	1 tablet SL once daily	Administer first dose in health care setting and monitor for at least 30 minutes. Subsequent doses may be given at home.

Administer first dose in a health care setting because of the potential for allergic reactions; monitor patient for 30 minutes after first dose. If well tolerated, subsequent doses may be taken at home. Autoinjectable epinephrine should be made available to patients. Place tablet(s) under tongue until completely dissolved (at least 1 minute) and then swallow. Wash hands after handling the tablet. Avoid

food or beverage for 5 minutes following dissolution of tablet (to prevent the swallowing of allergen extract).

BAU, bioequivalent allergy unit; IR, index of reactivity; SL, sublingually.

BIOLOGIC THERAPY FOR ALLERGIC RHINITIS

There are currently no biologic therapies with an approved indication for allergic rhinitis. Biologic therapies are FDA approved for the add-on treatment of very poorly controlled persistent asthma despite the use of conventional therapies such as inhaled corticosteroids and long-acting bronchodilators. Several biologic agents exist that interfere with the inflammatory cascade and include anti-IgE, anti-IL-5, and anti-IL-4.

Anti-IgE Therapy

Omalizumab is a recombinant humanized monoclonal anti-IgE antibody that binds free circulating IgE in the body preventing binding to receptors on mast cells and basophils.[40] Currently, this therapy is FDA approved only for people age 6 years or older with moderate-to- severe allergy-related asthma inadequately controlled with inhaled corticosteroids; however, off-label use is allergic rhinitis. Omalizumab has shown efficacy at decreasing serum IgE levels, improvement in daily nasal symptom scores and quality of life, and a decrease in rescue antihistamine use.[40] Omalizumab is also approved for patients age 12 years or older with chronic idiopathic urticaria who remain symptomatic despite H_1 antihistamine treatment. This product has a high cost (estimated to be between $6400 and $32,000 per patient per year).[35] The product has a boxed label warning to alert users that it can cause potentially life-threatening allergic reactions after any dose, up to 24 hours after the dose is given, and even if there was no reaction to the first dose. Ongoing monitoring is recommended to better determine rates of malignancies related to long-term use of omalizumab.[41]

Anti-IL-5 and Anti-IL-4

Reslizumab, mepolizumab, benralizumab (anti-IL-5), and dupilumab (anti-IL-4) have all been studied in small allergic rhinitis studies. These agents have promise, but further investigation is needed[40] as the efficacy and safety of these drugs for the treatment of allergic rhinitis need to be confirmed. Also, a pharmacoeconomic perspective must be carefully considered when identifying patients in whom these therapeutic targets will be options in the future.

Special Considerations of Medications in Pregnancy

The majority of data about the fetal risks of various pharmacotherapies are derived from animal studies. There are limited human data; however, cohort and case-control studies have been used to support therapeutic decision-making. Antihistamines, intranasal steroids, and cromolyn are considered safe to use during pregnancy.[3] Oral decongestants should generally be avoided,[3] although topical decongestants may be used on a short-term basis.[35] With limited human data available, oral montelukast is categorized as “probably compatible” with pregnancy[35]; however, generally, topical drugs are recommended over systemic therapy. Pregnant patients currently using immunotherapy may continue; however, initiation or an increased dose of immunotherapy during pregnancy is contraindicated.[3]

Nondrug Therapies

Supportive care is the foundation of treatment for patients with symptoms of rhinitis.[1] These strategies can be helpful during an acute worsening of symptoms as well as for the patient who suffers chronically. Supportive care can ameliorate discomfort, relieve mild symptoms, and assist with side effects from pharmacotherapies. Examples include the application of compresses to the sinuses or

external nasal passages and humidification of mucous membranes with artificial tears or nasal saline solutions. Many patients with chronic symptoms of rhinosinusitis report subjective improvement with nasal saline douching[3,5] or irrigation.

SPECIFIC THERAPEUTIC OPTIONS

Antihistamine Therapy

DIAGNOSIS OF ALLERGIC RHINITIS

CASE 20-1

QUESTION 1: L.B. is a 57-year-old male with a history of hypertension for 10 years and intermittent allergic rhinitis since childhood (confirmed sensitivity to birch tree pollen via skin testing). L.B. presents with nasal itching, sneezing, and clear rhinorrhea. He states he also has occasional stuffiness. He usually experiences similar symptoms, as well as ocular itching every spring, but has noticed that the problem has become persistent since he moved into an older home in the historic district of town 6 months ago. In the past, L.B. has successfully self-medicated his seasonal symptoms with an OTC antihistamine and decongestant (diphenhydramine 50 mg and pseudoephedrine 60 mg twice a day to four times a day as needed for symptoms), although "nothing seems to help much with the itchy eyes." L.B.'s hypertension has been well controlled with hydrochlorothiazide 25 mg and amlodipine 10 mg every morning. He denies any other medical problems, is afebrile, and his blood pressure is 128/82 mm Hg. He has no history of adverse drug reactions or drug allergies. He does not smoke but drinks alcohol socially.

What elements of L.B.'s presentation indicate a probable diagnosis of allergic rhinitis?

L.B. is exhibiting the classic symptoms of persistent (perennial) allergic rhinitis with intermittent (seasonal) exacerbations: nasal itching, sneezing, watery (often profuse) rhinorrhea, and congestion.[4] His history of positive skin tests and that his symptoms previously responded to antihistamine or decongestant[2] also support the diagnosis. In the past, L.B. has experienced symptoms predictably at

the onset of the tree pollination season, with only minimal symptoms during the remainder of the year. Moving into an older home, however, has likely triggered latent sensitivities to dust mite allergens and mold spores. A treatment approach can be developed based on these presumptions. If this strategy is not effective, skin-prick testing or additional laboratory assessments are warranted.

ALLERGEN AVOIDANCE MEASURES

Case 20-1, Question 2: What allergen avoidance strategies could L.B. use to minimize his exposure to triggers?

Allergen avoidance is important for reducing symptoms in patients with known sensitivities. Avoiding these triggers should lead to an improvement of symptoms; however, the use of a single physical or chemical method is not recommended.[29] To achieve effective control, a multifaceted approach to the control of environmental triggers is usually needed.[29] Although total allergen avoidance is often impractical to implement, simple changes that can reduce exposure to many perennial triggers, such as house dust mites, animal dander, and mold, may assist with symptom control.[1,9]

Dust mite avoidance (eg, the use of impermeable covers on box springs, mattresses, and pillows) has traditionally been used as a method of reducing allergen exposure. Although this practice continues to be recommended frequently, it is controversial. Studies have shown less dust mite levels in mattresses with impermeable covers, but this has not been correlated to improvement in symptoms.[1] Other methods of reducing antigen exposure include washing bedding at least weekly in hot water >130 °F (>55 °C) and dried under high heat in an electric dryer,[42] removing upholstered furniture, and washing floors daily.[1] Also, reducing humidity in the house to <50% and replacing carpets with linoleum, tile, or wood floors are commonly recommended.[42]

Mold avoidance is difficult when outdoor humidity levels are high, but covering cold, moist surfaces such as water pipes with insulation

and increasing ventilation can help reduce humidity. Also, visible mold should be removed from surfaces with detergent and water, and any embedded mold should also be removed.[42] Because L.B. has recently moved into an older home, he may not have used these avoidance strategies. These should be recommended and explained during the initial clinical consultation.

THERAPEUTIC OBJECTIVES FOR ALLERGIC RHINITIS

CASE 20-1, QUESTION 3: What are the therapeutic goals in treating L.B.?

The therapeutic goals for the treatment of allergic rhinitis are to control symptoms and permit all usual daily activities with no adverse effects of therapy. In patients with seasonal exacerbations, another goal is to prevent the onset of symptoms by anticipating the patient's season of sensitivity. In L.B.'s case, he should use daily environmental measures to reduce exposure to dust mites and mold and also begin chronic treatment. He may benefit from add-on therapy instituted 2 weeks before the start of birch tree pollen season.

CHOICE OF THERAPEUTIC AGENT

CASE 20-1, QUESTION 4: L.B. has used diphenhydramine for many years with good symptom relief and, as he recalls, only minimal daytime sedation. He asks your opinion regarding whether this is the best treatment for his allergy symptoms. He specifically requests an oral option that is the most cost-effective treatment available, because he must pay cash out-of-pocket for any medications. What therapy do you recommend and how should it be initiated?

Based on effectiveness and convenience, including nonprescription availability, oral antihistamines are the most frequent initial therapy recommended for patients with allergic rhinitis, particularly those with mild symptoms.[1] They reduce symptoms of nasal itching, sneezing, and rhinorrhea,[3] as well as ocular symptoms but offer no benefit for nasal congestion. FGAs (eg,

diphenhydramine, brompheniramine, chlorpheniramine, and clemastine) lack specificity for the H_1 receptor and can cause significant sedation, various anticholinergic side effects, can impair performance,[34] and are dosed multiple times per day, all of which limit their usefulness. Although at times these effects are considered desirable (eg, to aid in sleep and dry nasal secretions), the SGAs (eg, loratadine, fexofenadine, cetirizine, desloratadine, and levocetirizine)[35] are preferable in most instances.[1–3,43]

Antihistamines block the effects of histamine by one of two mechanisms: (a) as an H_1-receptor antagonist and (b) as an inverse agonist of the H_1-receptor.[4] FGAs cross the blood–brain barrier (BBB) leading to unwanted adverse effects. The nonsedating antihistamines (second- and third-generation agents) do not cross the BBB[4] and therefore are less sedating and preferred for small children and the elderly. L.B. has experienced a good response to an FGA without excessive drowsiness. However, sedation includes both drowsiness (ie, the subjective state of sleepiness or lethargy) and impairment (ie, an objective decrease in specific physical or mental abilities),[4] and cognitive impairment can occur[4] even in the absence of overt drowsiness. Although patients can exhibit tolerance to sedative properties of FGAs, they may not perceive the performance impairment that is still present. This has led to a consensus opinion among experts that SGAs are preferred to FGAs when treating allergic rhinitis.[1,3,5]

Essentially, all the antihistamines listed in Table 20-2 are equally effective.[2] Therefore, the choice of agent is based on the duration of action, side-effect profile (especially drowsiness and anticholinergic effects), risk of drug interactions, and cost.[1] Some patients claim that a kind of “tolerance” to the therapeutic effects occurs with antihistamines, in that with consistent use over time they perceive less symptomatic relief. Although no pharmacologic explanation exists to support these observations, patients may experience benefit from switching therapies if this perception presents.[1]

The major advantages of SGAs are their selectivity to the H_1-receptor and their reduced central nervous system sedative

effects.[9,35] Desloratadine, fexofenadine, loratadine, and levocetirizine—at recommended doses—are reported to have no sedating effects.[9] Loratadine and desloratadine can cause sedation at higher than recommended doses.[9] Cetirizine[9] and levocetirizine[1] have more sedation potential than the other second-generation agents.[9] Another advantage of SGAs is that most products can be dosed once daily[9] to improve patient adherence to therapy. Specific antihistamines are compared in Table 20-2. Maximum benefit is seen with continued use of oral antihistamines, but intermittent use may provide relief for many individuals.[1] In the case of L.B., it would be reasonable to begin therapy with loratadine 10 mg daily because as an SGA it has demonstrated efficacy with minimal side effects and is also available as an oral option without a prescription (as he requested) and as a generic formulation, which will further control costs.

INTRANASAL ANTIHISTAMINES

Case 20-1, Question 5: L.B. reports that a friend with similar symptoms had experienced relief from an antihistamine nasal spray. Is it possible to give antihistamines by this route, or is L.B. confusing this with other topical therapies such as decongestants or corticosteroids? Are intranasal antihistamines appropriate for L.B.?

Topical formulations are available for intranasal use. These are considered to be equal in efficacy to oral SGAs[1,26] with a quicker onset of action.[3] Also, they may improve congestion.[1,3] The intranasal antihistamines (azelastine and olopatadine) have a faster onset of action than oral agents[1] but unfortunately require twice-daily dosing.[9] Intranasal azelastine can also cause local side effects, including nasal irritation, dry mouth, sore throat, and mild epistaxis. An objectionable bitter aftertaste is a significant problem, occurring in up to 20% of patients.[3]

A potential role for intranasal antihistamines is for patients who do not respond adequately to oral antihistamines.[1] In addition, some patients may prefer the intranasal route of administration or benefit

from concomitant therapy with intranasal antihistamines and intranasal corticosteroids. As a prescription-only product, an intranasal antihistamine (even if available generically) would be more expensive than many oral alternatives. Because of the expense associated with prescription-only status, increased risk of side effects, and possibly objectionable taste, topical azelastine is not an optimal therapeutic option for L.B. at this time.

Decongestant Therapy

Case 20-1, Question 6: What role do decongestants have in L.B.'s treatment?

Nasal congestion is often much less severe in patients who experience only intermittent symptoms, but as L.B.'s symptoms have become persistent since his move, the exact frequency and severity of his nasal congestion should be assessed before recommending drug therapy. In patients with only mild, intermittent symptoms, saline irrigation (administered as frequently as needed) is helpful in soothing and moisturizing irritated nasal mucosa but may be impractical. Oral antihistamines do little to relieve nasal congestion; therefore, patients with moderate-to-severe congestion may require a combination of an antihistamine with a decongestant. The combination of an oral antihistamine and an oral decongestant is more effective than either component alone in the treatment of allergic rhinitis.[1]

Both the topical (intranasal) and the oral decongestants are sympathomimetics that directly stimulate α_1-adrenergic receptors, resulting in vasoconstriction.[35] Local effects on the nasal mucosa include reduced turbinate swelling and congestion[4] and improved nasal airway patency.[1] Oral decongestants include phenylephrine and pseudoephedrine. Until 2005, pseudoephedrine was the more popular agent; however, because of the potential to use it in the manufacture of illicit substances (eg, methamphetamine), restrictions

on the allowable quantity and methods for purchasing pseudoephedrine-containing products have been implemented at both the state and federal levels. These restrictions have resulted in the reformulation of many oral decongestant products to include phenylephrine as an alternative decongestant. These agents have no effect on sneezing, pruritis, or ocular symptoms.[4] The available oral and topical decongestants, some of which are available without a prescription, are compared in Table 20-3.

Oral decongestants can cause systemic side effects, particularly those associated with central nervous system stimulation (eg, nervousness, insomnia, tremor, anxiety, and panic attacks).[35] Cardiovascular stimulation (eg, tachycardia, palpitations, and increased blood pressure) can also occur, so patients with hypertension should be monitored carefully while taking oral decongestants.[25] Because oral decongestants are not associated with the development of rebound congestion, in most patients they are appropriate for intermittent short-term use but not chronic use.[29] Topical administration of decongestants generally does not lead to systemic side effects; however, these agents are not appropriate for chronic use in rhinitis because of their potential for causing rebound congestion (see Case 20-7 [Question 1]).

Because L.B. states occasional nasal congestion, he will require a decongestant in addition to the loratadine. He may choose to use a once-daily fixed-dose combination product (eg, loratadine 10 mg plus pseudoephedrine extended-release 240 mg), or it may be best for L.B. to supplement the daily loratadine with as needed pseudoephedrine. Although L.B. has used pseudoephedrine in the past without a problem, he may require education regarding procedures for purchasing this product, while assuring him that the restrictions are not related to the drug's safety as a decongestant. In addition, although his hypertension is controlled, his blood pressure should be monitored regularly to detect any effect. If L.B. is ready to consider a nonoral option, an intranasal steroid (discussed subsequently) would also be a reasonable option for him.

Ocular Therapies

RELATIONSHIP BETWEEN OCULAR AND NASAL SYMPTOMS

Case 20-1, Question 7: L.B.'s new therapies are effective for his persistent nasal symptoms; however, in the spring, he states that his eyes are itchy and watery and that the loratadine and pseudoephedrine do not seem to be helping. How are L.B.'s ocular symptoms related to his allergic rhinitis?

The most common forms of allergic ocular disorders are intermittent (seasonal) allergic conjunctivitis (SAC) and persistent (perennial) allergic conjunctivitis (PAC).[44] The symptoms of both SAC and PAC are identical in that they are caused by allergic response in the conjunctiva to airborne allergens. SAC symptoms are often linked to temporal exposure patterns of airborne environmental allergens like tree pollen (early spring), grasses (May–July), and weed pollens and outdoor molds (August–October).[44] Symptoms from PAC are triggered by single or multiple indoor allergens including animal dander, molds, and dust mites. The symptoms of allergic conjunctivitis are itchy eyes, redness, and swelling of the conjunctiva.[44]

Because of the potential for long-term damage to vision, persistent ocular conditions should always be assessed by an eye care professional. Other ocular problems that can be confused with allergic conjunctivitis include atopic keratoconjunctivitis and vernal keratoconjunctivitis, giant papillary conjunctivitis, and contact blepharoconjunctivitis[44] (see Chapter 54, Eye Disorders).

CHOICE OF THERAPEUTIC AGENT

Case 20-1, Question 8: What are the treatment options for L.B.'s allergic conjunctivitis, and how does the clinician choose between the available options?

Seasonal and perennial allergic conjunctivitis are treated similarly with only the duration of the treatment course differing (ie, episodic

vs chronic treatment). Nonpharmacologic treatment includes avoidance of aeroallergens to the extent possible, cold compresses,[45] and lubrication with frequent application of artificial tear substitutes to provide a barrier to and dilute various allergens and inflammatory mediators on the ocular surface.[46] The available therapeutic options for the management of allergic conjunctivitis include topical ocular administration of antihistamines, decongestants (vasoconstrictors), mast-cell stabilizers, and nonsteroidal anti-inflammatory drugs (**Table 20-5**).[45] These ocular medications act by the mechanisms similar to their nasal counterparts. In addition, topical ophthalmic corticosteroids have a limited role in the acute management of allergic conjunctivitis; however, they are not indicated for prolonged use because of the risk of serious infectious complications in the eye.[46]

Table 20-5
Topical Ophthalmic Medications Commonly Used for Allergic Conjunctivitis

Generic Name (Example Brand Product)	Available Dosage Forms/Strength	Dose
Antihistamines		
Azelastine (Optivar®)	Ophthalmic solution: 0.05%	Adults and children 3 years or older: 1 drop in the affected eye(s) every 12 hours
Emedastine (Emadine®)	Ophthalmic solution: 0.05%	Adults and children 3 years or older: 1 drop in the affected eye(s) up to four times daily
Epinastine (Elestat®)	Ophthalmic solution: 0.05%	Adults and children 2 years or older: 1 drop in the affected eye(s) twice daily
Antihistamine/Decongestant Combinations		
Pheniramine + Naphazoline (Naphcon-A®, Opcon-A®, Visine-A®)[a]	Ophthalmic solution: naphazoline HCl 0.025% + pheniramine maleate 0.3%	Adults and children 6 years or older: 1–2 drops in the affected eye(s) up to four times/day for up to 3 days

Antihistamine/Mast-Cell Stabilizers		
Ketotifen (various brand names)[a]	Ophthalmic solution: 0.025%	Adults and children 3 years or older: 1 drop in the affected eye(s) every 8–12 hours
Olopatadine (Pataday®, Patanol®, Pazeo®)	Ophthalmic solution: 0.1%, 0.2%, 0.7%	0.1%: Adults and children 3 years or older: 1 drop in affected eye(s) twice daily at an interval of 6–8 hours 0.2% and 0.7%: Adults and children 2 years or older: 1 drop in the affected eye(s) once daily
Alcaftadine (Lastacaft®)	Ophthalmic solution: 0.25%	Adults and children 2 years or older: 1 drop in each eye once daily
Bepotastine (Bepreve®)	Ophthalmic solution: 1.5%	Adults and children 2 years or older: 1 drop in the affected eyes(s) twice daily
Mast-Cell Stabilizers		
Cromolyn Sodium (Crolom®)	Ophthalmic solution: 4%	Adults and children 4 years or older: 1–2 drops in the affected eye(s) four to six times daily
Lodoxamide (Alomide®)	Ophthalmic solution: 0.1%	Adults and children 2 years or older: 1–2 drops in the affected eye(s) four times daily
Nedocromil (Alocril®)	Ophthalmic solution: 2%	Adults and children 3 years or older: 1–2 drops in the affected eye(s) twice a day
Nonsteroidal Anti-Inflammatory Drugs[b]		
Ketorolac (Acular®)	Ophthalmic solution: 0.5%	Adults and children 2 years or older: 1 drop in the affected eye(s) four times daily
Corticosteroids[c]		
Loteprednol (Alrex®)	Ophthalmic suspension: 0.2%	Adults: 1 drop in the affected eye(s) four times daily

[a]Available without a prescription.

[b]Other ophthalmic nonsteroidal anti-inflammatory drugs (diclofenac, flurbiprofen, and suprofen) indicated for intraoperative miosis and for postcataract surgery but not approved for allergic conjunctivitis.

[c]Other ophthalmic corticosteroids (dexamethasone, difluprednate, triamcinolone, and fluorometholone) indicated for ocular inflammation but not approved for allergic conjunctivitis.

Source: Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home.

In the case of L.B., a trial of antihistamine plus vasoconstrictor combination eye drops (eg, pheniramine maleate 0.3% plus naphazoline hydrochloride 0.025%) one to two drops in the affected eye(s) up to four times a day for the management of acute symptoms is an appropriate recommendation for short-term use. Note that the overuse of ocular vasoconstrictors can lead to rebound conjunctivitis, similar to that occurring with nasal decongestants (see Drug-Induced Nasal Congestion: Rhinitis Medicamentosa section). As a result, the use of a topical ophthalmic decongestant should be limited to 3 to 5 days. If the patient exhibits chronic symptoms, consider a switch to an intranasal corticosteroid (which may have better efficacy for combination symptoms)[1] or refer to specialist care.

Cromolyn Therapy

CASE 20-2

Question 1: J.C. is a 10-year-old girl who has been experiencing rhinorrhea and sneezing during visits to her father's home in another state for 3 weeks at a time a couple of times each year. On questioning, J.C.'s mother reveals that although J.C. has not had symptoms in the past, her father adopted a puppy from the local animal shelter about a year ago, and the symptoms only correspond to the times that the child spends with the dog. J.C. will be visiting her father again next month, and she is hoping to purchase something without a prescription to prevent her from "getting sick and missing out on her summer vacation."

What options are available to treat J.C.'s intermittent symptoms of allergic rhinitis?

These symptoms may reflect mild, intermittent allergic rhinitis triggered by exposure to animal dander. When it is possible to anticipate symptoms, as in J.C.'s case, initiating prophylactic therapy

can help lessen the impact of allergen exposure.[42] Although intermittent use of antihistamines or intranasal corticosteroids are commonly selected options, intranasal cromolyn sodium administered regularly beginning several weeks before each trip may also offer benefit in this situation. Because the mother indicates that she wants to select an OTC product, allergen avoidance strategies plus cromolyn nasal spray would be a reasonable choice for initial therapy. The drawbacks to this are its out-of-pocket cost, its technique-dependent administration, its multiple daily dosing requirements (up to six times daily),[29] and its reduced effectiveness compared with other treatments.[3]

Case 20-2, Question 2: What strategies should J.C.'s father use to minimize exposure to the allergic triggers?

To minimize J.C.'s exposure to allergens, the dog should be kept out of the child's bedroom at all times and, when possible, kept outside or confined to an uncarpeted area of the home.[47] J.C.'s father should vacuum the home with a HEPA filter and double thickness bag vacuum system while J.C. is out of the house. Although evidence of benefit is unclear, it may be helpful to wash the dog at least twice a week while the child visits.[47] Similarly, after touching or playing with the dog, J.C. should wash her hands especially before touching her face[48] and should change and wash clothes regularly.[47] The additional expense of regular, commercial cleaning of air ducts is not cost justified.

INSTRUCTIONS FOR USE

Case 20-2, Question 3: How should J.C. be advised to use cromolyn nasal spray to prevent her symptoms?

To be effective, cromolyn nasal spray must be dosed several times each day, which can hinder adherence.[43] The initial dose for the cromolyn sodium nasal spray (5.2 mg/actuation) is one spray in each

nostril three to four times a day up to six times daily.[34] In some patients, symptom control can be maintained with dosing two to three times per day. J.C. should be instructed to begin therapy at least 2 weeks before her planned visit because of the delay in the onset of action for this agent with a known trigger exposure (dog dander).[49]

The clinician should ensure that both parent and child can demonstrate appropriate administration technique before therapy is initiated. On first use, the device should be primed until a consistent fine mist spray is achieved. J.C. should be instructed to gently blow her nose and then spray the cromolyn sodium solution into each nostril in a slightly upward direction, parallel to the nasal septum.

Topical nasal cromolyn has an excellent safety profile, including minimal incidence of adverse effects. Local irritation with burning, stinging, and sneezing are the most common manifestations. The safety of cromolyn[49] has made it widely used as initial therapy for children with allergic rhinitis and for treating rhinitis during pregnancy. **Table 20-6** includes information about intranasal cromolyn dosing and availability.

Table 20-6
Additional Oral and Intranasal Agents for Rhinitis

Generic (Brand Product)	Available Dosage Forms/Strength	Adult Dose	Pediatric Dose
Oral			
Leukotriene modifiers Montelukast (Singulair®)	Tablets: 10 mg Tablets, chewable: 4 mg, 5 mg Oral granules: 4 mg	10 mg once daily	Children ≥6 to <15 years: 5 mg once daily Children 6 months to <6 years: 4 mg once daily (chewable tablet or granules)
Intranasal			
Antihistamine Azelastine (Astepro®)	Nasal spray: 0.1% 0.15%	Perennial: 0.15%: 2 sprays/nostril twice daily Seasonal: 0.1%: 1–2 sprays/nostril twice daily 0.15%: 1–2 sprays/nostril twice daily or 2 sprays/nostril once daily	Perennial: Children 6 months–5 years (0.1%) 1 sp each nostril (EN) bid Children 6–11 years: 0.1% or 0.15%: 1 spray/nostril twice daily Seasonal: Children 6–11 years: 0.1% or 0.15%: 1 spray/nostril twice daily Children 2–5 years: 0.1%: 1 spray/nostril twice daily
Olopatadine (Patanase®)	Nasal solution: 0.6%	Seasonal: 2 sprays/nostril twice daily	6 to <12 years: 1 spray/nostril twice daily
Mast-cell stabilizer Cromolyn sodium (Nasalcrom®)[a]	Nasal spray: 5.2 mg/spray	1 spray/nostril three to four times/day (every 4–6 hours; max six times daily)	Children 2 years or older: 1 spray/nostril three to four times/day (every 4–6 hours; max six times daily)
Anticholinergic Ipratropium bromide (Atrovent®)[b]	Nasal spray: 21 µg/spray (for perennial symptoms), 42 µg/spray (for seasonal symptoms)	2 sprays/nostril 3 to 4 times daily (max 672 µg/day)	Children 6 years or older: 42 µg/spray: 2 sprays/nostril two to three times/day Children 5–11 years: 84 µg/spray: 2 sprays/nostril three times daily

[a]Available without a prescription.

[b]Optimum dosage varies with the response of the individual patient. It is always desirable to titrate an individual to the minimum effective dose to reduce the risk of side effects. In addition, the safety and efficacy of the use of ipratropium 42 µg nasal spray beyond 3 weeks in patients with seasonal allergic rhinitis not been established.

Intranasal Corticosteroid Therapy

CASE 20-3

QUESTION 1: A.R. is an 8-year-old girl with allergic rhinitis and asthma. She is being treated with inhaled budesonide for asthma and oral loratadine for rhinitis. Her mother reports that she frequently sneezes, has an itchy nose and eyes, and does not sleep well at night because of nasal congestion. She also reports that she cannot give her cetirizine daily because it "makes her drowsy at school." Her asthma has been well controlled in the past; however, lately, she is concerned that she is experiencing some shortness of breath, and it may be related to her allergies. While you are talking to her, you note that A.R. breathes

exclusively through her mouth, sniffs frequently, and rubs her nose. You also notice dark circles under her eyes.

What signs and symptoms of allergic rhinitis is A.R. displaying?

A.R. is showing the classic signs of allergic airways disease in children. She is sniffing and snorting in response to nasal itching and discharge. The frequent upward rubbing of the nose (generally with the palm) is known as the "allergic salute"[1] and is caused by nasal itching. Long-standing symptoms can lead to facial abnormalities, including the formation of a transverse crease across the bridge of the nose.[3] Dark circles under the eyes are commonly known as "allergic shiners," and they can be further aggravated by the frequent rubbing of the eyes associated with severe ocular itching.[1,3]

CASE 20-3, QUESTION 2: Given her concomitant asthma, are there any special considerations for treating A.R.'s allergic rhinitis?

Based on the relationship between inflammation in the upper and lower airways, and the similar immunologic mechanisms involved in allergic rhinitis and asthma, it is a reasonable assumption that poor control of upper airway allergies can have a negative impact on asthma control.[29] In fact, rhinitis is a risk factor for asthma development,[43] and poorly controlled rhinitis can aggravate asthma control.[4] In a patient with asthma, like A.R., treatment of allergic rhinitis can also reduce airway hyperresponsiveness and symptoms of asthma.[1,43] Historically, the use of antihistamines (FGAs) was considered problematic for patients with asthma because of a theoretic concern about excessive drying of airway secretions caused by the anticholinergic properties of these agents. It is now clear that most patients with asthma can take any of the antihistamines without adverse pulmonary effects as AR has done in the past. Intranasal corticosteroids should be considered for A.R. as they are considered first line for patients with concomitant allergic rhinitis and asthma.[6]

ROLE IN THERAPY

Case 20-3, Question 3: What would be the role of intranasal corticosteroids in A.R.?

Based on the frequency and severity of symptoms, the lack of control/side effects with oral antihistamine therapy, and concomitant asthma, intranasal corticosteroids are appropriate consideration for A.R. Intranasal corticosteroids are the most effective therapy available for the treatment of allergic rhinitis. They are safe, well tolerated, and are highly effective in reducing itching, sneezing, rhinorrhea, and congestion in both adults and children.[1] In addition to improving all nasal symptoms, evidence suggests that intranasal administration of corticosteroids effectively relieves ocular symptoms.[43] These agents also have demonstrated efficacy for nonallergic rhinitis,[9] rhinitis medicamentosa (RM),[50] and nasal polyps.[51] The currently available intranasal corticosteroids are listed in **Table 20-7**.

Table 20-7
Intranasal Corticosteroids[a] Commonly Used for Rhinitis

Generic Name (Example Brand Product)	Available Dosage Forms/Strengths	Adult Dose[a]	Pediatric Dose[a]
Beclomethasone dipropionate (Beconase AQ®), QNASL (HFA)®, QNasal (Children's)®	42 µg/spray 80 µg/spray 40 µg/spray	42 µg: 1–2 sprays/nostril twice daily 80 µg: 2 sprays/nostril once daily	Children 6–12 years: 42 µg: 1 spray/nostril twice daily (max 2 sprays/nostril daily) Children 4–11 years: 40 µg: 1 spray/nostril once daily
Budesonide (Rhinocort Aqua®, Rhinocort Allergy®, Children's Rhinocort®)	32 µg/spray	1 spray/nostril once daily (max 4 sprays/nostril daily)	Children 6 to <12 years: 1 spray/nostril once daily (max 2 sprays/nostril daily)
Ciclesonide (Omnaris®), Zetonna (HFA®)	50 µg/spray 37 µg/spray	50 µg: 2 sprays/nostril once daily 37 µg: 1 spray/nostril once daily	50 µg: Children 6 to <12 years: 2 sprays/nostril once daily (approved for seasonal symptoms in ages older than 6 years and for perennial symptoms for ages older than 12 years) 37 µg: do not use in children younger than 12 years.
Fluticasone propionate (Flonase Allergy Relief®, Clarispray®, Children's Flonase®, GoodSense Nasoflow®, Ticaspray®)	50 µg/spray	2 sprays/nostril once daily or 1 spray/nostril twice daily	Children 4–11 years: 1–2 sprays/nostril once daily (max 2 sprays/nostril daily)
Fluticasone furoate (Flonase Sensimist® and Veramyst®)	27.5 µg/spray	2 sprays/nostril once daily	Children 2–11 years: 1 spray/nostril once daily (max 2 sprays/nostril daily)
Flunisolide (no brand product available)	0.025%	Older than 15 years: 2 sprays/nostril two or three times daily (max 8 sprays/nostril daily)	Children 6–14 years: 1 spray/nostril three times daily or 2 sprays/nostril twice daily (max 4 sprays/nostril daily)
Mometasone furoate (Nasonex®)	50 µg/spray	2 sprays/nostril once daily	Children 2–11 years: 1 spray/nostril once daily
Triamcinolone acetonide (Nasacort AQ®, Nasacort Allergy®)	55 µg/spray	2 sprays/nostril once daily	Children 2–5 years: 1 spray/nostril once daily (max 1 spray/nostril daily) Children 6–11 years: 1–2 sprays/nostril once daily (max 2 sprays/nostril daily)
Azelastine HCl/fluticasone propionate (Dymista®)	137/50 µg/spray	1 spray/nostril twice daily	Children 6 years or older: 1 spray/nostril twice daily

[a]It is always desirable to titrate an individual patient to the minimum effective steroid dose to reduce the risk of side effects. When the maximum benefit has been achieved and symptoms have been controlled, reducing the steroid dose might be effective in maintaining control of rhinitis symptoms.

Source: Data from Facts & Comparisons eAnswers. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home.

Intranasal corticosteroids are the most effective agents to treat allergic rhinitis regardless of concomitant asthma. They are more effective than other available therapeutic options. They are frequently rated as more effective than antihistamines,[1] although the benefit from therapy requires correct use of the administration device.[3] Intranasal corticosteroids improve congestion, sneezing, rhinorrhea, itching,[42] and ocular symptoms[52] with no difference in efficacy among the available options.[1]

MECHANISM OF ACTION

Case 20-3, Question 4: How do intranasal corticosteroids work to reduce the symptoms of allergic rhinitis?

Corticosteroids readily diffuse across cell membranes, where they bind to a specific steroid receptor in the cytoplasm of a cell, and the steroid–receptor complex then moves into the cell nucleus, where it influences protein synthesis and inhibits the breakdown of phospholipids to arachidonic acid.[52] This, in turn, inhibits the formation of prostaglandins and leukotrienes. Topical corticosteroids reduce the number of eosinophils, basophils, and mast cells in the nasal mucosa and epithelium; directly inhibit the release of mediators from mast cells and basophils; reduce mucosal edema and vasodilation; and stabilize the endothelium and epithelium, resulting in decreased exudation.[1] Topical corticosteroids inhibit both the early-phase and late-phase reactions to antigen challenge,[35] and therefore pretreatment and continued use are recommended.[1]

CHOICE OF THERAPEUTIC AGENT

Case 20-3, Question 5: What intranasal corticosteroid products are appropriate to manage A.R.'s allergic rhinitis?

Currently marketed intranasal corticosteroid products vary in the pharmacologic characteristics that can influence patient acceptance and adherence; however, there do not appear to be significant advantages with regard to efficacy among them.[1] Primary differences among products include potency, dosing regimens, delivery systems, spray volume,[34] and patient preference. For sensitive patients, there may be some theoretical advantage to products that are preservative or alcohol-free.

The ideal intranasal corticosteroid agent should exhibit high topical potency and low systemic activity. After topical administration, the corticosteroid may reach the systemic circulation by absorption across the nasal mucosa or through gastrointestinal absorption of the swallowed portion of the dose.[44] Studies have shown that varying

sensory attributes (eg, aftertaste, nose runout, and smell) affect acceptability of, and preference for, particular nasal corticosteroid products.[1] Some degree of experimentation may be required to find the optimal product for A.R.

SAFETY

Case 20-3, Question 6: How safe are intranasal corticosteroids in this situation?

The corticosteroids currently available for intranasal administration are listed in Table 20-7. Among available products, intranasal corticosteroids have similar efficacy in clinical trials.[1] Budesonide, beclomethasone, ciclesonide, and flunisolide are indicated for age 6 years or older. Beclomethasone HFA and fluticasone propionate are labeled for age 4 years or older, and mometasone, triamcinolone, and fluticasone furoate are indicated in children age 2 years or older.[34] Triamcinolone (Nasacort Allergy 24 hour®), fluticasone propionate (Flonase Allergy Relief®), budesonide (Rhinocort®), and fluticasone furoate (Flonase Sensimist®) are available OTC. Because A.R. is 8 years old, theoretically she is a candidate for any of the OTC intranasal steroids; however, given her concomitant asthma, a prescription agent may be a better choice. Because poor control of upper airway allergies can have a negative impact on asthma control,[29] proper monitoring by her provider is important.

A common concern regarding the use of corticosteroids in children is the risk of growth suppression. Current U.S. FDA labeling for inhaled and intranasal corticosteroid preparations include wording that use of these products in children may reduce their rate of growth. Although beclomethasone may be associated with reduced growth velocity,[34] numerous studies have shown no growth delay in children treated long term with newer intranasal steroids.[1] Specifically, studies with mometasone, fluticasone, budesonide, ciclesonide, and triamcinolone have shown little clinical effect on growth at recommended doses.[53] It is always judicious to

recommend and utilize the lowest effective dose of intranasal corticosteroids especially in a pediatric population also on a concomitant inhaled corticosteroid agent. Because A.R. has concomitant asthma, this may be the case in this patient.

Other potential adverse effects of chronic intranasal corticosteroids have been investigated. Severe local effects such as nasal mucosal atrophy or septal ulceration are rarely seen and can be prevented with appropriate technique.[53] Changes in bone mineral density, intraocular pressure, or cataracts do not appear to be of concern.[53]

INSTRUCTIONS FOR USE

CASE 20-3, QUESTION 7: A.R. is given a prescription for budesonide, two actuations in each nostril twice daily. How should she be counseled to use this drug?

Although intranasal corticosteroids have an excellent safety profile, some local adverse effects can occur. The currently available products are all aqueous solutions delivered via a manual spray pump; these are much less drying than the original propellant-based aerosol formulations of the same products. The most commonly reported side effect is epistaxis.[51] Local irritation, burning, stinging, and dryness are also possible.[1] Proper technique in using nasal corticosteroid products can reduce the risks for these side effects.[1]

Patient education is important to ensure proper use of, and response to, the intranasal corticosteroids.[5] A.R. should be instructed to blow her nose gently before using the nasal spray as severe blockage of the nasal passage may prevent deposition of the drug at the intended site of action. The patient should be instructed to direct the spray away from the nasal septum.[42] This technique is facilitated by using the contralateral hand during administration to each nostril. This results in pointing the applicator nozzle straight and back to ensure application is parallel to the septum.[3]

Therapeutic benefit to intranasal steroids is generally evident in a few days,[3] although some newer agents may begin to relieve symptoms within hours because of a quick onset of effect.[1] Fluticasone has been effective when used on an as-needed basis.[1] Nonetheless, it is reasonable to advise patients that full benefit may not be realized for up to 2 weeks.[3]

Systemic Corticosteroids

Case 20-3, Question 8: What is the role of systemic corticosteroid therapy in the management of A.R.'s allergic rhinitis?

In contrast to the minimal side effects of the topical corticosteroids, systemic administration of these drugs can cause numerous, and at times serious, side effects. Systemic administration, therefore, must be reserved for only short-term, adjunctive therapy in cases of severe, debilitating rhinitis. In such cases, a short course of relatively high-dose corticosteroid, so-called burst therapy, can be administered. Prednisone 40 mg/day for adults or 1 to 2 mg/kg/day for children (or an equivalent dose of a comparable compound) every morning for up to 7 days effectively relieves acute, severe rhinitis symptoms. If A.R. were to have a particularly severe exacerbation of her allergic rhinitis such that it interfered with sleep or ability to attend school, an oral corticosteroid burst would be indicated. More likely, A.R. would require a short course of systemic corticosteroids for an acute asthma exacerbation, which should also result in improved nasal symptoms.

Combination Therapy

Case 20-3, Question 9: Would there be an advantage in combining various therapies for allergic rhinitis in A.R.?

The rationale for combining agents to treat allergic rhinitis is based on the theoretic benefit of additive or synergistic reactions. Various combinations have been studied. Concomitant use of antihistamines and decongestants has been shown to relieve individual nasal symptoms compared with either agent alone. Combining intranasal antihistamines and intranasal corticosteroids also is beneficial.[1] However, the combination of intranasal corticosteroids with oral antihistamines has not been shown to offer clinical benefit over use of intranasal steroids alone.[1] Similarly, the combination of oral antihistamines and leukotriene modifier therapy is generally not recommended.[1] As A.R. has concomitant asthma, recent guidelines concur that an intranasal corticosteroid is preferred monotherapy over combinations with oral agents. However, the addition of montelukast may be considered, given her asthma history.[6] When combination therapy of any kind is used, once symptoms are controlled, one agent should undergo a trial for discontinuation.

Leukotriene-Modifying Agent Therapy

CASE 20-4

Question 1: K.H. is a 58-year-old male with allergic rhinitis. He has experienced symptoms during ragweed pollen season (<4 weeks out of the year) for several years. He has used various antihistamines including clemastine and diphenhydramine for his symptoms during these times with moderate success. This year, he initiated therapy with diphenhydramine 1 week before the pollen season but began experiencing symptoms of urinary retention after 10 days. His physician advised him that this might be related to the antihistamine aggravating his enlarged prostate, and he was advised to use fexofenadine 60 mg twice daily. After 1 week, K.H. states that the medication is not working. After seeing an advertisement on television, he enquires about the use of a leukotriene modifier for his allergic rhinitis.

What is the mechanism for K.H.'s urinary discomfort attributed to the diphenhydramine?

K.H. is exhibiting symptoms of urinary outflow obstruction or prostatism. Common features of this are frequency, hesitancy, slow

urine stream, dribbling, and bladder fullness after voiding. The most common cause of obstruction is benign prostatic hyperplasia (BPH). Because the prostate is located anatomically around the urethra, enlargement of the gland can obstruct urine flow.[54]

The bladder and urethra are made up of smooth muscle tissue that is innervated by the sympathetic and parasympathetic divisions of the autonomic nervous system. The detrusor musculature is predominantly innervated by β-adrenergic and cholinergic receptors, whereas the bladder neck (or outlet) is innervated predominately by α-adrenergic receptors.[55] Sympathetic stimulation causes relaxation of the detrusor muscle to allow bladder filling, closure of the urethra, and decreased bladder emptying. Cholinergic stimulation of the detrusor causes contraction of the detrusor to cause bladder emptying. Initially, the detrusor musculature can compensate for the urethral obstruction in BPH. Eventually, however, the detrusor muscle fibers hypertrophy and decompensate, resulting in urinary retention and detrusor hyperreflexia manifesting as urinary frequency, urgency, urge incontinence, and nocturia.[56]

When K.H. took diphenhydramine, the anticholinergic properties of the drug blocked detrusor contraction and precipitated acute urinary retention.[55] In this case, switching therapy to an SGA (ie, fexofenadine) is more appropriate because these agents have little to no anticholinergic side effects.

EFFICACY

Case 20-4, Question 2: What are the rationale and evidence that a leukotriene modifier might be beneficial in the management of K.H.'s allergic rhinitis?

Leukotrienes are important inflammatory mediators in the upper and lower airways and are present in nasal secretions of patients with allergic rhinitis. They serve as inflammatory mediators that attract eosinophils and increase microvascular leakage, edema, and mucus gland secretion.[4] These actions lead to the symptoms of

allergic rhinitis as well as those of asthma.[29] In clinical trials, leukotriene modifiers relieve nasal symptoms in patients with allergic rhinitis however not as well as nasal corticosteroids.[1]

In actual use, the benefit of leukotriene modifiers has been modest; therefore, their role is typically adjunctive to the use of first-line agents (eg, intranasal steroids), and these are not recommended first line for allergic rhinitis.[1] Other therapies are more effective and less costly. There are, however; certain patient scenarios where leukotriene modifiers have a role in therapy. Clinical decisions about the value of combining treatments regimens that include a leukotriene-modifying agent should be based on the specific clinical situation. Specifically, a patient with both mild asthma and concomitant allergic rhinitis may benefit from therapy with a leukotriene modifier[6] with or without an antihistamine.[35] If used, however, a risk exists of a rare complication known as eosinophilic granulomatosis with polyangiitis (formerly known as Churg-Strauss). This syndrome is characterized by eosinophilia, vasculitic rash, worsening pulmonary symptoms, cardiac complications, and neuropathy.[34] Table 20-6 includes information about the use and availability of montelukast, which is currently the only leukotriene modifier approved for allergic rhinitis. Montelukast carries a boxed warning related to mental health adverse events including completed suicides. This strengthens the recommendation that montelukast not be considered first line for allergic rhinitis.[34] K.H. has intermittent (seasonal) allergic rhinitis with a known trigger (ragweed pollen). The best option at this time would be to ideally start before ragweed season with an intranasal steroid. Since ragweed season has already hit, and patient is symptomatic, the use of Intranasal steroid (INS) is still recommended first line. The use of montelukast should be discouraged for K.H. as it plays a limited role in seasonal allergic rhinitis, and is not generally recommended for patients with persistent disease either.

Complementary and Alternative Therapies

CASE 20-5

QUESTION 1: C.L., a 25-year-old female, presents in mid-August stating that her allergies are worsening daily. Symptoms are nasal discharge and obstruction, repetitive sneezing, and itching of the nose, eyes, and throat. She is fatigued and has difficulty concentrating. Her symptoms have been occurring in late spring and summer since high school, and she has used a variety of medications intermittently (clemastine, fexofenadine, beclomethasone nasal, and ketotifen ophthalmic) over the years. C.L. is a competitive runner but has been unable to run as far or as often as usual because of bothersome allergy symptoms. She is also reluctant to use traditional Western medications as they may be prohibited by her race sponsors. A running partner mentioned that she could control her allergy symptoms with diet, exercise, and herbal remedies purchased at a local nutritional supplement shop.

What, if any, alternative treatments are efficacious in allergic rhinitis?

Alternative treatments such as yoga, massage, acupuncture, homeopathy, and herbal therapy are common among adults with rhinitis and should be taken into account by health care providers. Literature indicates that 25% to 50% of the general population and up to 70% of children have used an alternative method at least once.[57] The estimated lifetime prevalence of complementary and alternative medicine (CAM) use among patients with allergic rhinitis is high; between 27% and 46%. Acupuncture is used by ~18% of patients with allergic rhinitis. Still, because allergic rhinitis is largely a self-managed disease, it is likely that reported use of these agents is underestimated. A survey found that only 43% of subjects who had used alternative methods had informed their provider about it.[57] For these reasons, patients should always be questioned specifically about the use of alternative therapies during the patient interview. Although some alternative approaches such as acupuncture have been deemed to be safe,[1,51] the safety and efficacy of herbal remedies has not been clearly established and cannot be recommended at this time[1] although their use is quite popular.[58] In addition, some complementary therapies have been associated with side effects and potential drug interactions.[57] Because of C.L.'s reluctance to use traditional Western medications, other strategies are appropriate to consider to help manage her rhinitis symptoms.

Camphor and menthol-delivered rubs (Vicks VapoRub®, Breathe Right Colds Nasal Strips®) have been shown to have an ameliorating effect on nasal congestion[59]; however, the effects are short-lived.[34] Other forms of aromatherapy suggested to relieve nasal congestion are lacking data related to efficacy.[59] Saline nasal irrigation (eg, neti pot) is simple, inexpensive, and has been shown to have some efficacy.[60]

PHYSICAL TECHNIQUES

Acupuncture

Clinical trial data show patients with allergic rhinitis who use acupuncture have seen an improvement in quality of life and antihistamine use.[61] The clinical significance of these findings remains uncertain; however, some experts do recommend that clinicians offer this treatment modality to patients who are interested.[1]

HERBAL MEDICINES

It has been suggested that some herbs have anti-allergy, immune modulation, and anti-inflammatory effects that may be helpful to ease symptoms of allergy.[62] With this in mind, *Echinacea* has become one of the top-selling herbal products in the United States. *Echinacea*, also known as the purple cornflower, however, is a member of the daisy Compositae (Asteraceae) family.[63] Although *Echinacea* is often used for immune-related disorders, patients with known allergy to these plants should be cautioned regarding the use of *Echinacea* products.

A few herbal therapies, including butterbur, biminne, Chinese herbal mixture,[1] and spirulina[64] potentially hold some promise because of positive results in trials on clinical symptoms and quality of life in patients with allergic rhinitis, but more investigation is needed before they can be included in recommended treatment algorithms.[1]

OTHER

Reports regarding the use of intranasal zinc for upper respiratory symptoms, particularly those associated with the common cold, and congestion associated with allergies have been conflicting. Although zinc gels and sprays are popular OTC products, studies show inconsistent results[65] and may be associated with zinc-induced anosmia syndrome.[65] Some products have been removed from the market because of this problem. By giving patients minuscule amounts of allergen, homeopathic medicines are designed to mimic and augment a patient's own immune responses and natural defenses.[66] Some studies have shown that patients with allergic rhinitis who received homeopathic dilutions of allergens had significantly better nose running scores than those in the placebo group.[66] Further investigation is needed before homeopathy can be recommended for allergic rhinitis.

Although a variety of alternative remedies are widely available and used frequently in self-treatment, based on the evaluation of these data, there is no firm recommendation for C.L. regarding the use of alternative therapies in allergic rhinitis.[1] C.L. should be advised to consult with the specific regulating agency that governs her sporting activities (eg, the World Anti-Doping Agency for Olympic events) to gain a clear understanding of medicines that are banned in all cases as compared to those that may be used with medical exemptions or used outside of the competitive window. This may allow her to use many conventional treatments (eg, intranasal steroids) with confidence. Saline irrigation or acupuncture would also be a safe, noncontroversial option that may offer some efficacy.

Immunotherapy

EFFICACY

CASE 20-6

Question 1: R.C. is a 25-year-old schoolteacher who has experienced allergic symptoms since childhood, but noticed a worsening after she graduated from college and moved to a new area of the country. Although she has mild

symptoms year-round, she has severe exacerbations during April through June and August through October each year. During these periods, she feels that exposure to cut grass and weeds provokes profound nasal symptoms. She also notes that when she spends more time outdoors in spring and early fall, the regular therapy that she buys OTC, fluticasone (Flonase®) nasal spray (two sprays per nostril once daily), is less effective. She has added loratadine (10 mg daily) during this time but is frustrated by having to take so many medications while continuing to experience symptoms. Her administration technique and adherence to the INS are both good. R.C. asks your opinion about allergy shots, remarking that she started them as a child with some relief, but moved after a year and never resumed treatment.

Is allergen immunotherapy effective for reducing symptoms of allergic rhinitis?

Allergen-specific immunotherapy has long-standing and long-term efficacy, induces clinical and immunologic tolerance, and may prevent the progression of allergic disease.[67] Immunotherapy is available via SCIT (sometimes called “allergy shots”) or sublingual tablets (SLIT).[68] Sublingual aqueous drops[68] are also sometimes used but are not FDA approved in the United States.[1] Immunotherapy is unique and capable of changing the course of the disease.[1] By giving dilute solutions of allergen-containing extracts in repeated and increasing doses, immunologic tolerance is provided.[67] Therefore, subsequent exposure to those allergens elicits no or mild symptoms. Immunotherapy has been shown to improve symptom scores and quality of life.[69]

Immunotherapy administered via SCIT has been used empirically since the early 1900s, and its efficacy has been documented in many controlled trials.[70] SIT is effective in the treatment of allergic rhinitis and may even prevent the onset of asthma.[1] In addition, the benefit of immunotherapy is long-lived. Even after discontinuation, studies show continued beneficial effects up to 10 years later.[1] SCIT and SLIT should be considered a supplement to drug therapy in specific patients and possibly be used earlier in the course of allergic disease to achieve maximal benefit.[1,71]

ALLERGEN TESTING

Case 20-6, Question 2: How can the clinician determine R.C.'s specific sensitivities?

Skin testing using the modified prick test method or a prick-puncture method is used to confirm the diagnosis of allergic rhinitis[72] and to determine specific allergen sensitivities. Skin testing is a highly sensitive and relatively inexpensive objective measurement of allergen sensitivity. Small quantities of allergen are introduced into the skin by pricking or puncturing the skin in the immediate presence of the diluted allergen extract. Fifteen to 35 tests are placed on the upper portion of the back or the palmar surface of the forearms. A positive skin test produces a wheal-and-flare reaction at the site within 10 to 20 minutes of application and should be read after 15 minutes.[73] An experienced clinician, usually an allergist, should conduct skin testing using high-quality allergen extracts and should interpret the results.[73]

The allergens tested vary with geographic location, emphasizing the most common offending plant species that generate airborne particles. Pollen, the primary particle, is produced by trees, grasses, and weeds. Each of these plant groups generally pollinates at about the same time each year: trees in the spring, grasses from early to midsummer, and weeds from late summer into fall before the first killing frost. The onset and potency of the pollen season vary with geographic location and weather, particularly with respect to temperature and moisture. It is postulated that climate change is also affecting pollen and weed seasons. For example, ragweed is projected to have a much greater impact on patients living across the eastern United States in the future owing to increases in climate variability.[24] Seasonality of symptoms can be misleading because settled pollen particles from a previous season may be resuspended in the air following the spring snowmelt or periods of heavy winds.

Mold spores are also common airborne allergens. The outdoor molds release their spores from early spring through late fall. Within this long season, spore counts increase and decrease, depending on the presence of local flora on which these molds grow (eg, grain and

other crops, forests, and orchards). Some perennial allergens (eg, house dust mites, insect and animal dander, and some indoor molds) occur consistently across all geographic distributions.

In addition to skin-prick testing, clinicians can detect allergen-specific IgE antibodies in the blood.[74] Results are reported quantitatively and total serum IgE can be useful in determining if atopy is present[75] and will help determine which allergen extracts should be utilized if allergen immunotherapy is desired.[75] In each case, skin test results[62] or IgE serum levels[63] must be correlated with the patient's clinical history as it may help assess prognosis and inform treatment decisions[75.] R.C.'s perennial symptoms with seasonal exacerbations indicate sensitivity to the common perennial allergens such as dust mite, with a particular sensitivity to seasonal allergens such as tree, grass, and weed pollen. These subjective relationships should be confirmed with skin-prick testing.

Case 20-6, Question 3: R.C. is currently using medications (fluticasone nasal spray and loratadine) for her symptoms. Should these be discontinued before skin testing?

Antihistamines blunt the wheal-and-flare reaction by blocking the effects of histamine on capillaries. Different antihistamines vary in the extent to which they can inhibit wheal formation and in the duration of the inhibitory effect with older first-generation agents being the worst offenders.[73] Other agents that may interfere with skin-prick testing include long-term systemic corticosteroids, topical (dermal) corticosteroids, tricyclic antidepressants,[76] phenothiazine-type antipsychotics, antiemetics,[73] and possibly some herbal preparations.[76] Depending on the agent selected, antihistamines must be discontinued from 24 hours to 10 days before skin testing,[73] and even then considerable interpatient variability exists in blocking effects. For best results, R.C.'s loratadine should be discontinued 10 days before her skin testing. Recommendations for discontinuing antihistamines before allergen skin testing are listed in **Table 20-8**.

Table 20-8

General Recommendations for Discontinuation of Antihistamines Before Allergen Skin Testing

1. Remind the patient that allergic symptoms may return during the antihistamine-free period, but that reliable skin tests cannot be performed in a patient currently taking antihistamines.
2. Discontinue any short-acting antihistamine (ie, those in Table 20-2 with a duration of suppression ≤4 days) 4 days before skin testing.
3. Discontinue longer-acting antihistamines (ie, those in Table 20-2 with a duration of suppression >4 days) at an interval appropriate to their duration of effect (eg, hydroxyzine should be discontinued 10 days before skin testing).
4. Before applying the full battery of skin tests, apply histamine (positive) control and glycerinated diluent (negative) control tests. Application of a 1 mg/mL histamine base equivalent should yield wheal-and-flare diameters of 2–7 mm and 4.5–32.5 mm, respectively, to be considered a normal histamine reaction. A normal cutaneous reaction to histamine control suggests that accurate skin testing can be performed.

Source: Bousquet J, Khalteav N, Cruz AA, et al. Allergic rhinitis and its impact on asthma (ARIA) 2008 update (in collaboration with the World Health Organization, GA(2) LEN and AllerGen). *Allergy*. 2008;63(suppl 86):8-160. Reprinted by permission of John Wiley & Sons, Inc.

Other allergy medications, including cromolyn and nasal corticosteroids, have no effect on skin tests. Likewise, most asthma medications, including leukotriene modifiers, inhaled β_2-agonists, cromolyn, theophylline, and inhaled and short-course systemic (burst) corticosteroids have no effect on skin tests.[73] R.C. can continue the use of fluticasone nasal spray as she waits to be skin tested.

Case 20-6, Question 4: Is R.C. a candidate for immunotherapy injections and/or sublingual tablets?

Immunotherapy via SCIT or SLIT should be offered to patients who have an inadequate response to pharmacologic treatment for AR with or without environmental controls.[1] Further considerations are the patient's preference, adherence, response to avoidance measures, adverse drug effects, and coexistence of allergic asthma.[1]

It has also been shown that the clinical benefits of immunotherapy are similar if not better than standard therapy with intranasal steroids, montelukast, or antihistamines.[71] In the case of R.C., she has year-round symptoms with seasonal exacerbations, she has not experienced symptom relief when using appropriate therapies, and she is motivated to try immunotherapy. In addition, a previous trial in childhood was beneficial. For these reasons, skin-prick testing and a trial of immunotherapy with specific allergens are reasonable.

LENGTH OF THERAPY

Case 20-6, Question 5: If R.C. decides to proceed with immunotherapy, how long should her therapy continue and how long will the effects last?

After identifying the offending allergens via skin testing, subcutaneous immunotherapy is generally administered in two phases. During the build-up phase, increasing doses of allergen are given once or twice a week until a predetermined target or maintenance dose is achieved. Once this maintenance dose is reached, shots are usually administered every 2 to 3 weeks for the ensuing several years of treatment. Clinical improvement with immunotherapy usually occurs in the first year. In a small percentage of patients, there is no improvement, and immunotherapy is discontinued. If symptoms are reduced, however, injections are usually continued for 3 to 5 years of maintenance therapy.[77]

Although immunotherapy can lead to long-term remission of symptoms, one drawback is the lengthy treatment period. SCIT and SLIT have disease-modifying properties, and clinical benefits can persist 2 to 3 years after discontinuation of therapy.[78] Both SLIT and SCIT are effective for allergic rhinitis. They both reduce symptoms and the need for medication. Both SLIT and SCIT are being studied to determine their effectiveness for preventing other atopic disease states like asthma.[79] Immunotherapy via sublingual tablet involves placing the tablet under the tongue for 1 to 2 minutes before swallowing. There is no titration schedule. See Table 20-4 for dosing

information and when best to initiate therapy in relation to the allergen season. A benefit of the sublingual tablet form of immunotherapy is only the first dose needs to be administered in the provider's office, compared to every dose with SCIT.[77] Patients, however, need to be adherent because these sublingual tablets require daily dosing. Choice of formulation often is determined by patient convenience, availability of resources (ability to travel to allergist office), and personal preference,[78] so RC would need to discuss these with her provider.

RISKS

Case 20-6, Question 6: What are the risks associated with either the shot or the sublingual tablet?

Local adverse reactions (ie, redness, local itching, and swelling of the mouth)[78] to SCIT can be common, but the risk of severe reaction (ie, anaphylaxis) is low.[1] Sublingual tablets are FDA approved for self-administration after the first dose because of the perceived safety profile. Because of the risk of anaphylaxis, patients should have access to and be taught the proper technique for an epinephrine autoinjector.[1] Because of the occasional occurrence of systemic side effects, it is important that if R.C. receives SCIT, it should be administered by office personnel who are fully trained and experienced in the early recognition and treatment of such reactions.[78]

Case 20-6, Question 7: Should R.C. also have a prescription for an epinephrine injector for use in case of anaphylaxis? If so, how should it be used?

Yes, if R.C. decides to use SLIT, she will need a prescription for and education on how to administer injectable epinephrine. She should be educated to use the injection of epinephrine if signs or symptoms (such as facial itching, tongue swelling, difficulty

swallowing, or shortness of breath) occur after a dose of SLIT. The autoinjector is given intramuscularly into the thigh, through clothing if necessary. R.C. can repeat the injection with an additional epinephrine autoinjector as necessary.[34] See **Table 20-9** for available injectable epinephrine products.

Table 20-9
Available Injectable Epinephrine Products

Product Name	Dosage Form and Strength	Injection Site	Injection Hold Time	Adult Dose	Pediatric Dose	Generic Available?
EpiPen (2 Pak)®	Solution autoinjector 0.3 mg/0.3 mL	Outer middle of thigh	3 seconds	≥30 kg: 0.3 mg IM or SQ	0.15 mg for 33–66 pounds (15–30 kg)	Yes
Auvi-Q®	0.1 mg/0.1 mL 0.15 mg/0.15 mL 0.3 mg/0.3 mL auto injector (includes voice prompts)		2 seconds	≥30 kg: 0.3 mg IM or SQ	0.1 mg for 16.5–33 lb (7.5–15 kg) 0.15 mg for 33–66 lb (15–30 kg)	No
Symjepi®	0.3 mg/0.3 mL prefilled syringe 0.15 mg/0.3 mL prefilled syringe		2 seconds	≥30 kg: 0.3 mg IM or SQ	0.15 mg for 33–66 pounds (15–30 kg)	No
EpiPen Jr (2 Pak)®	Solution autoinjector 0.15 mg/0.3 mL		3 seconds	N/A	0.15 mg for 33–66 pounds (15–30 kg)	Yes

IM, intramuscularly; SQ, subcutaneously.

DRUG-INDUCED NASAL CONGESTION: RHINITIS MEDICAMENTOSA

CASE 20-7

Question 1: L.K. is a 27-year-old male who has intermittent allergic rhinitis. He reports that his symptoms are most bothersome in the spring and associated with blooming of various grasses. During these past periods, he has used oral chlorpheniramine (4 mg every 6 hours), which relieves his symptoms but makes him drowsy at work. This season, he reports that his symptoms have been more severe, with sneezing, runny nose, and extreme itching in his nose. He tried oral loratadine (10 mg daily) with partial relief of symptoms. He also states that nasal congestion has been more of an issue with this episode and to address

this he has used oxymetazoline nasal spray (0.05% solution) for the past 3 weeks. Despite increasing the use of nasal spray from the OTC recommended dosages of two sprays per nostril twice daily to three sprays per nostril four times a day, he reports that the congestion is getting worse.

What might be an explanation for L.K.'s increasing need for nasal decongestant?

Selected medications and some drugs of abuse can cause nasal congestion through a variety of mechanisms.[50] **Table 20-10** lists agents associated with drug-induced nasal symptoms. In this case, L.K. is likely experiencing rebound nasal congestion because of a specific form of drug-induced rhinitis called rhinitis medicamentosa (RM).

Table 20-10

Drugs Capable of Causing Nasal Symptoms

Local Inflammatory Mechanisms
Aspirin
Nonsteroidal anti-inflammatory drugs
Neurogenic Mechanisms
Centrally Acting Sympatholytics
Clonidine
Methyldopa
Reserpine
Peripherally Acting Sympatholytics
Prazosin
Guanethidine
Doxazosin
Phentolamine
Vasodilators
Sildenafil
Tadalafil
Vardenafil

Idiopathic Mechanisms
Antihypertensives
Amiloride
Angiotensin-converting enzyme inhibitor class
β-Blocker class
Calcium channel blockers
Chlorothiazide
Hydralazine
Hydrochlorothiazide
Hormonal Products
Exogenous estrogens
Oral contraceptives
Neuropsychotherapeutic Agents
Alprazolam
Amitriptyline
Chlordiazepoxide
Chlorpromazine
Gabapentin
Risperidone
Perphenazine
Thioridazine

Topical decongestants are indicated for short-term use. When used acutely, these drugs cause vasoconstriction by acting on α-adrenergic receptors on blood vessels.[80] This serves to relieve nasal congestion associated with edematous, congested blood vessels, but, when these agents are used chronically, this can result in

overstimulation of α-adrenergic receptors leading to tachyphylaxis and decreased production of endogenous norepinephrine through a negative feedback mechanism.[80] RM has also been associated with the presence of benzalkonium chloride as a preservative in some nasal products.[80]

When RM occurs, many patients will attempt to treat the rebound congestion by using the offending topical decongestant more frequently and/or at increased doses, creating a vicious cycle. L.K.'s description of using the oxymetazoline for an extended period of time (3 weeks), more frequently (from twice daily to four times daily), and at high doses (from two sprays per nostril to three sprays per nostril) support the diagnosis of RM.

Case 20-7, Question 2: How should L.K.'s RM be managed?

Strategies for Resolution

The best strategy for managing RM is prevention by limiting the duration of topical decongestant use to no more than 3 to 5 days.[34] When these medications must be used for longer than 5 days, the patient should be advised to take a 1- to 2-day holiday during which the topical agent is not used before resuming treatment. Patients should be counseled about this whenever topical decongestants are recommended or purchased. When preventative strategies fail, several options for treatment exist.[80]

The first step is to discontinue the offending topical decongestant. L.K. should be counseled to stop the oxymetazoline. Because abrupt discontinuation may cause discomfort or worsening of congestion, L.K. should be educated to not restart the topical decongestant.[80] Intranasal corticosteroids (any available product) should be recommended to patients with RM and may need 6 weeks to reach full effect.[80] Because L.K. is experiencing RM plus symptoms (sneezing, runny, and itchy nose) that occur seasonally, an IN corticosteroid such as mometasone nasal spray (two sprays in each nostril daily) should be recommended. Saline nose drops or spray

can be added to moisturize and alleviate any nasal irritation. In refractory cases, a short course of systemic corticosteroids (prednisone) may be necessary.[80] Note that if the patient has used the topical decongestant continuously for many months or even years, the nasal mucosa may have undergone irreversible changes.

IDIOPATHIC RHINITIS

Diagnosis

CASE 20-8

Question 1: M.S. is a 29-year-old male with profuse watery rhinorrhea that has been a chronic and progressively worsening problem for the past 5 years. He also experiences some nasal congestion with the rhinorrhea but denies nasal itching or sneezing. Although the symptoms tend to remit and exacerbate, they do not occur in any definable seasonal pattern. His symptoms are worsened by exposure to tobacco smoke, strong fumes such as paint or ammonia, and cold air. These often are associated with headaches. M.S. has no other medical problems and no family history of allergies. He does not smoke and rarely drinks alcohol. His only medication, mometasone (50 µg/spray, two sprays in each nostril once daily as needed), only partially relieves the symptoms. M.S. sniffs and blows his nose several times during the medical history taking. Physical examination reveals a mildly erythematous nasal mucosa and a minimally edematous inferior turbinate. Copious nasal discharge is clear and watery and air movement through the nose is relatively good. There is no sinus tenderness. The remainder of his physical examination is normal. Microscopic examination of a nasal smear demonstrates only a few neutrophils and no eosinophils.

What information about M.S. supports the diagnosis of idiopathic rhinitis?

Idiopathic rhinitis is a diagnosis of exclusion encompassing those patients with nasal mucous membrane inflammation with no clinical signs of infection (colored secretions) and no systemic signs of allergic inflammation (IgE in blood or nasal smear).[7] The syndrome is sometimes called nonallergic rhinitis or “vasomotor rhinitis,” but using this terminology can be confusing because the cause of the

symptoms has still not been clearly identified.[9] The prevailing theories involve local atopy, dysfunction of both or either the autonomic nervous system or nociceptive nerve sensor and ion channel proteins.[10] Theoretically, this is the reason that stimuli that normally increase parasympathetic activity in the nose, such as cold air and inhaled irritants, aggravate symptoms.[10] Still, substantial debate exists over whether idiopathic rhinitis represents a localized allergic response in the absence of systemic atopic markers as well as the evidence for inflammatory pathophysiology in the disease.[9]

Case 20-8, Question 2: What causes idiopathic rhinitis, and what can be done to alleviate M.S.'s symptoms?

The symptoms of idiopathic rhinitis are variable. Most patients experience perennial nasal obstruction accompanied by profuse, watery nasal, and postnasal discharge. Many patients have nasal obstruction as the primary symptom, whereas for others it is rhinorrhea. Sneezing, nasal itching, and conjunctival symptoms are rare.[10] Headache may occur and usually is frontal or localized over the bridge of the nose. Symptoms may also appear or worsen in response to climatic changes such as temperature, barometric pressure, and humidity.[10] Similarly, irritant triggers such as tobacco smoke, industrial pollutants, strong odors and perfumes, newsprint, and chemical fumes may worsen or aggravate symptoms.[10]

The appearance of the nasal mucosa also is variable. The turbinates are usually erythematous and, during an exacerbation, considerable quantities of nasal secretions, which can lead to crusting and dryness, may be present.[9] Nasal eosinophilia is not present, and skin-prick testing results are usually negative.[10]

M.S.'s symptoms of bothersome watery rhinorrhea, nasal congestion, and headache without itching or sneezing are typical. His worsening symptoms with exposure to noxious inhalants and cold air support the diagnosis of idiopathic rhinitis. The nasal smear, which notably lacks large numbers of eosinophils, initially differentiates this disease from NARES. This disorder has similar

symptoms but also is marked by nasal eosinophilia (5%–20%) in the setting of negative skin-prick testing and negative IgE levels.[10]

Choice of Therapeutic Agent

Case 20-8, Question 3: What nonpharmacologic and pharmacologic treatments are appropriate to manage M.S.'s idiopathic rhinitis?

Patients should be instructed to avoid as many aggravating factors as possible, such as strong odors (perfumes, soaps, and paints) and air pollutants (smoke and tobacco fumes).[9] Saline irrigation is valuable as a general soothing and moisturizing treatment.[9] Pharmacotherapy for idiopathic rhinitis should be directed toward the predominant symptoms of the individual patient. For patients with predominant nasal congestion and minimal rhinorrhea, intranasal corticosteroids may be helpful.[7] The addition of oral decongestants may improve nasal obstruction in some patients with idiopathic rhinitis but should be considered adjunctive therapy because side effects can be problematic and data regarding efficacy are lacking.[9]

M.S.'s case is typical of the often frustrating course in treating idiopathic rhinitis. Commonly, multiple therapeutic plans fail, and M.S. has responded incompletely and unsatisfactorily to intranasal corticosteroids. There is some older evidence suggesting topical nasal capsaicin may be effective, but this option has not garnered widespread support.[9] Surgical treatments have been attempted for patients in whom medical management fails, although it is typically reserved for patients with concomitant nasal septal deviation or turbinate hypertrophy.[9]

In patients such as M.S., who have rhinorrhea as their predominant symptom, FGAs may be helpful because of their anticholinergic drying effects.[9] The topical antihistamine, azelastine, has been shown to be efficacious for symptoms including congestion, postnasal drip, and sleeping difficulty in those with idiopathic rhinitis.[9] Another option for decreasing nasal secretions is nasal ipratropium bromide, a topical anticholinergic agent with

minimal adverse effects[9] (see Table 20-6 for dosing information). In the case of M.S., because he has been comfortable using an intranasal product (mometasone) in the past, it would be reasonable to initiate a trial of ipratropium bromide 0.03% two sprays in each nostril three times daily. Once the rhinorrhea is controlled, he should be advised to reduce the dosage to twice daily. Nasal saline can also be used as needed if excessive dryness occurs during dosage optimization.

CASE 20-9

QUESTION 1: D.W. is a 56-year-old female with a long-standing history of allergic rhinitis related to triggers with seasonal ragweed. Her primary symptoms are rhinorrhea and sneezing, which she has relieved by using various oral antihistamines (clemastine 1 mg daily and, more recently, cetirizine 10 mg daily) that she takes several weeks each autumn. Recently (during winter), she has experienced new rhinitis symptoms associated with the weather and various odors that were not a problem in the past, specifically, perfumes and food spices. When she encounters these, she exhibits watery rhinorrhea and profound congestion. She has tried a combination of cetirizine with pseudoephedrine for these episodes but reports that it "doesn't seem to help much and it makes me feel jumpy."

Are D.W.'s new symptoms the result of breakthrough (uncontrolled) allergic rhinitis or do they represent something new?

MIXED ALLERGIC–NONALLERGIC RHINITIS

Distinguishing between allergic rhinitis and nonallergic rhinitis may be difficult in clinical practice, and the presence of concomitant allergic and nonallergic rhinitis in some patients confounds the diagnosis further.[8] A careful history should be gathered from the patient and an assessment made of the temporal nature of the symptoms and various exposures. The Clinical Presentation and Assessment of Rhinitis section in this chapter can be helpful to review to help distinguish between allergic and nonallergic causes of rhinitis. When a patient presents with characteristics suggestive of

both types, especially in the case of new symptoms or triggers despite optimized therapy, mixed rhinitis should be considered.

Although D.W. has a confirmed history of ragweed pollen sensitivity (supporting the allergic rhinitis diagnosis), the timing of the more recent symptoms and the new triggers (ie, odors) suggest that she may have developed sensitivities of a nonallergic (non–IgE-based) nature. The patient's age also is consistent with the development of vasomotor rhinitis (nonallergic), which can present around the time of menopause. This, combined with the lack of efficacy from a previously successful therapy (ie, oral antihistamine), suggests that D.W. may be exhibiting a mixed allergic–nonallergic rhinitis presentation.

Case 20-9, Question 2: How should D.W.'s mixed rhinitis be treated? How is this different from the management of allergic rhinitis?

The important point about nonallergic triggers, or new onset triggers such as those present in D.W., is that oral antihistamines and other therapies directed primarily at allergic responses may be ineffective in relieving all symptoms. Good clinical evidence suggests that intranasal steroids are an effective option, as well as intranasal antihistamine therapy or a combination of the two.[1] Avoidance or minimization of exposure to the triggers is also an important strategy. For D.W., a 4-week therapeutic trial of a benzalkonium chloride-free intranasal steroid (eg, ciclesonide two sprays in each nostril once daily) with counseling about appropriate administration is warranted. Intranasal steroid therapy may improve the response to both allergic and nonallergic triggers.[1]

SUMMARY

The initial management of rhinitis should be directed at preventing symptoms, which can be achieved through a variety of pharmacologic and nonpharmacologic methods. Treatment plans for

allergic rhinitis, the most common subtype, should include patient education, allergen or irritant avoidance, and the appropriate medications, including immunotherapy if indicated. Control of the disease process is the expected outcome so that patients can live their lives comfortably without symptoms or impairment. Customizing therapy for each patient based on symptom history and response to treatments is important. Rhinitis can be controlled, and effective management can greatly improve the quality of patients' lives.

Cystic Fibrosis

Paul M. Beringer and Michelle Condren

CORE PRINCIPLES		CHAPTER CASES
1	Cystic fibrosis (CF) is a genetic disorder affecting ~30,000 individuals in the United States that is caused by a defect in the CF transmembrane conductance regulator protein, which is a chloride channel that regulates fluid and electrolyte transport within secretory epithelial cells throughout the body.	**Case 21-1 (Question 1), Figures 21-1, 21-2**
2	The principal manifestations of CF include malnutrition secondary to pancreatic insufficiency and pulmonary dysfunction resulting from chronic airway obstruction, infection, and inflammation.	**Case 21-1 (Question 1), Table 21-1**
3	Diagnosis of CF is based on newborn screening or the presence of the typical	**Case 21-1 (Questions 1, 2), Table 21-2**

	signs and symptoms of the disease, and either documented abnormalities in ion transport or identification of two CF mutations.	
4	Administration of pancreatic enzymes and fat-soluble vitamins is prescribed to correct malabsorption and vitamin deficiencies and improve nutritional status.	**Case 21-1 (Question 2), Table 21-3**
5	Key therapies for the management of CF pulmonary disease include cystic fibrosis transmembrane regulator (CFTR) modulator therapies to correct the basic defect, inhaled dornase alfa and hypertonic saline in combination with mechanical airway clearance techniques to combat airway obstruction, inhaled antibiotics to combat airway infection, and oral azithromycin for airway inflammation.	**Case 21-2 (Questions 1–3)** **Case 21-3 (Question 3)** **Case 21-3 (Question 6)**
6	Periodically, patients will experience acute pulmonary exacerbations characterized by increased pulmonary symptoms, acute loss of lung function, and loss of weight, which require intensification of airway clearance, administration of systemic antibiotics, and nutritional supplements.	**Case 21-3 (Questions 1, 2, 4), Table 21-4**
7	Key monitoring parameters in patients with CF include trends in pulmonary function tests to determine response to therapies and identify possible acute	**Case 21-1 (Question 3)**

	pulmonary exacerbations, and body mass index to assess nutritional status.	
8	Therapy for patients with CF should include attention to complications including CF-related diabetes mellitus, osteoporosis, hepatobiliary disease, constipation, and anxiety/depression.	**Case 21-3 (Question 5)**

INTRODUCTION

Cystic fibrosis (CF) is a severe, complex, hereditary disease that affects one in every 3200 Caucasian births, or ~30,000 children and adults in the United States. One in 31 Americans carries the autosomal recessive gene for CF, which arises from a mutation in coding for the CF transmembrane regulator (CFTR) protein. This genetic mutational error results in the complex, multisystem disease of CF, which is characterized by malabsorption and a state of chronic lung obstruction, inflammation, and infection.

The course and severity of CF are variable and unpredictable. The median predicted survival age has increased from 34 to 46 years over the past two decades owing to advances in the management of this disorder.[1] The recent availability of highly active CFTR modulators (eg, elexacaftor, tezacaftor, and ivacaftor) has created significant excitement in the CF community because of the dramatic improvements in clinical outcomes (eg, lung function and nutritional status) and is expected to significantly increase the life expectancy of people with CF.

GENETIC BASIS

CF is caused by mutations in the *CFTR* gene, which is a member of the ATP-binding cassette family. CFTR is dependent on cyclic adenosine monophosphate for chloride transport: defective coding for CFTR inhibits the normal regulation of ion transport in and out of the cell on the apical surface of secretory epithelial cells.[2] CFTR also regulates the transport of bicarbonate and sodium ions, mucous rheology, pulmonary inflammation, and bacterial adherence.[3–7]

CF is an autosomal recessive disorder, which means there is a 25% chance of inheriting the malfunctioning genes from both parents and developing the disease, a 50% chance of inheriting one abnormal gene (ie, carrier), and a 25% chance of inheriting two normal genes. Approximately 5% of Whites are asymptomatic carriers of the CF mutation. More than three decades have passed since the identification and cloning of the gene responsible for CF, and >2000 *CFTR* mutations have been discovered (https://www.cftr2.org). These mutations have been grouped into six major classes according to the functional consequence of the defect (**Fig. 21-1**).[8–10] However, this classification scheme is an oversimplification owing to the potential for multiple molecular defects caused by a single or combination of mutant alleles.[11] For example, the most common variant, F508del, exhibits impaired protein folding, leading to degradation within the endoplasmic reticulum consistent with a class II mutation. Administration of CFTR rescue therapies (eg, lumacaftor) allows the protein to reach the airway epithelial surface, where it exhibits a channel gating defect, consistent with a class III mutation. This complex molecular pathology is the basis for combination therapy with CFTR modulators (eg, elexacaftor, tezacaftor, and ivacaftor). In vitro models representing these complex mutations to test various combination therapies, “theratyping,” is an active area of drug discovery and development designed to identify the optimal treatment of people with rare CF mutations.

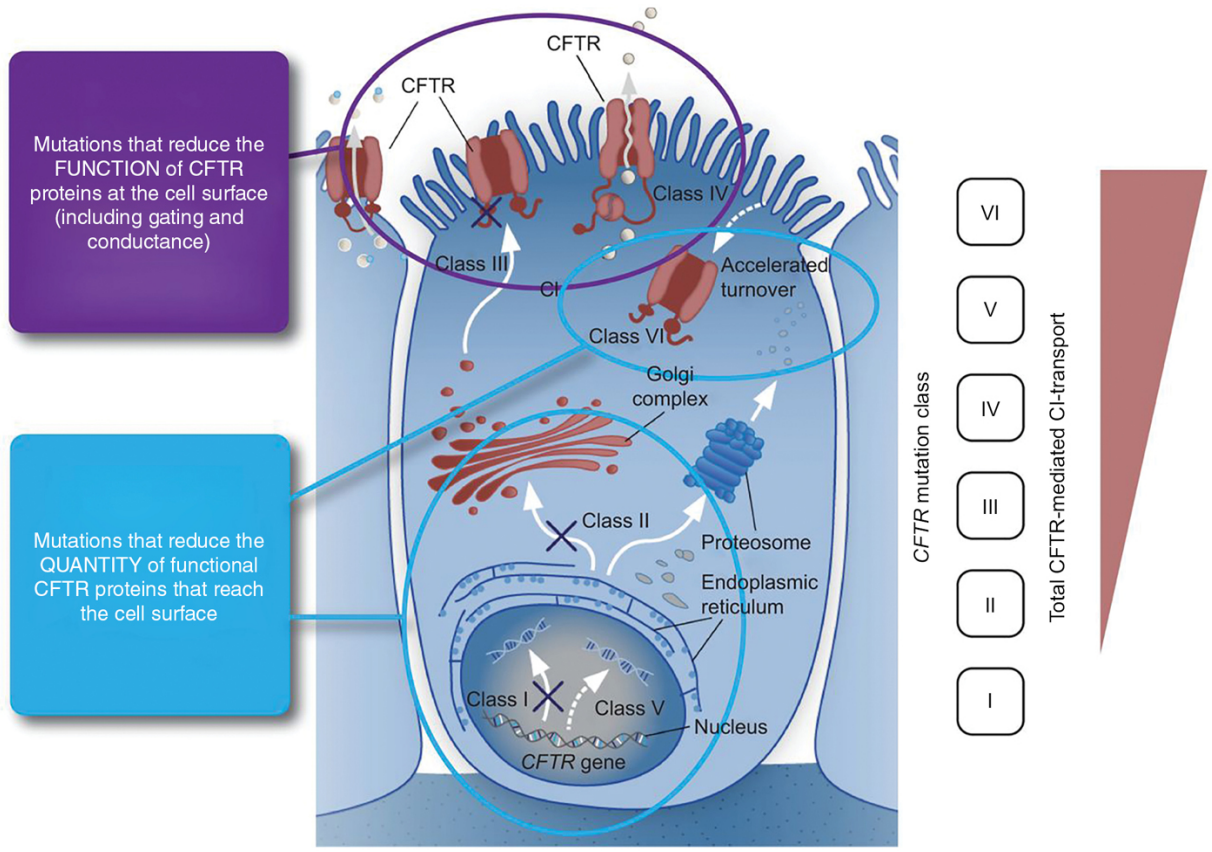

Figure 21-1 Classification of mutations. Class I mutations include those in which the production of the cystic fibrosis transmembrane regulator (CFTR) protein is blocked owing to *stop mutations.* Defective protein processing is responsible for the class II mutations. In this class, the protein is made, but it is unable to make its way from the endoplasmic reticulum to the apical membrane, where it is needed for proper operation. This includes the most common mutation, ΔF508, which is caused by improper folding of the protein. Class III mutations disrupt the channel to open properly. Class IV mutations are unable to achieve proper ion conduction. Class V is a milder form of class I mutations and includes mutations that cause reduced production of functional CFTR. Class VI mutations are characterized by a high turnover of CFTR at the cell surface. (Source: From Derichs N. Targeting a genetic defect: cystic fibrosis transmembrane conductance regulator modulators in cystic fibrosis. *Eur Respir Rev.* 2013;22(127):58–65.

doi:10.1183/09059180.00008412. Reproduced with permission of the © ERS 2022.)

Interestingly, even among individuals with identical genotypes, a broad spectrum of disease severity is seen.[12,13] The contribution of genetic factors other than the misfunctioning CFTR can have a great influence on disease severity.[14]

CLINICAL MANIFESTATIONS

Genotype, environmental factors, and modifier gene status all contribute to the highly variable clinical course of CF. The linking of the loss of CFTR function to clinical manifestations of the disease, however, has been central to gaining an understanding of the disease and in the discovery of new therapies. Normally, CFTR is highly expressed on the membranes of epithelial cells of the lungs, sweat glands, salivary glands, male genital ducts, pancreas, kidney tubules, and digestive tract. The CFTR performs different functions in specific tissues; therefore, a dysfunctional or absent CFTR has different effects on different organs, resulting in multiorgan clinical manifestations of CF (**Table 21-1**).

Table 21-1
Clinical Manifestations of Cystic Fibrosis

	Approximate Incidence (%)	
Manifestation	**Children (Infants)**	**Adults**
Pancreatic		
Insufficiency	85 (80–85)	90
Pancreatitis	1–2	2–4
Abnormal glucose tolerance	38	75
Diabetes mellitus	14	40–50
Hepatobiliary		

Biliary cirrhosis	10–20	>20
Cholelithiasis	5	5–10
Biliary obstruction	1–2	5
Intestinal		
Meconium ileus	20	
Meconium ileus equivalent	1–5	10–20
Rectal prolapse	10–15	1–2
Intussusception	1–5	1–2
Gastroesophageal reflux	1–5	>10
Appendiceal abscess	0–1	1–2
Respiratory		
Nasal polyps	4–10 (<1)	15–20
Pansinusitis		90–100
Bronchiectasis	30–50	>90
Pneumothorax	1–2	10–15
Hemoptysis	5–15	50–60
Reproductive		
Delayed puberty		85
Infertility		
Males		98
Females		70–80

Sweat Glands

Fluid secreted by the sweat glands in patients with CF is normal, but a defect in the reabsorption of electrolytes leads to sweat with high salt content. CFTR, in the apical membrane of the resorptive area of the sweat gland, functions as an ion channel for chloride transport and also activates an associated epithelial sodium channel.[15] Normally, these channels efficiently reabsorb sodium chloride from sweat. In people with CF, loss of these functioning channels blocks the ability of the sweat ducts to reabsorb salt, leading to elevated

sweat sodium chloride concentrations (**Fig. 21-2**). The loss of these sodium and chloride ion channels serves as the basis for the diagnostic sweat chloride test.

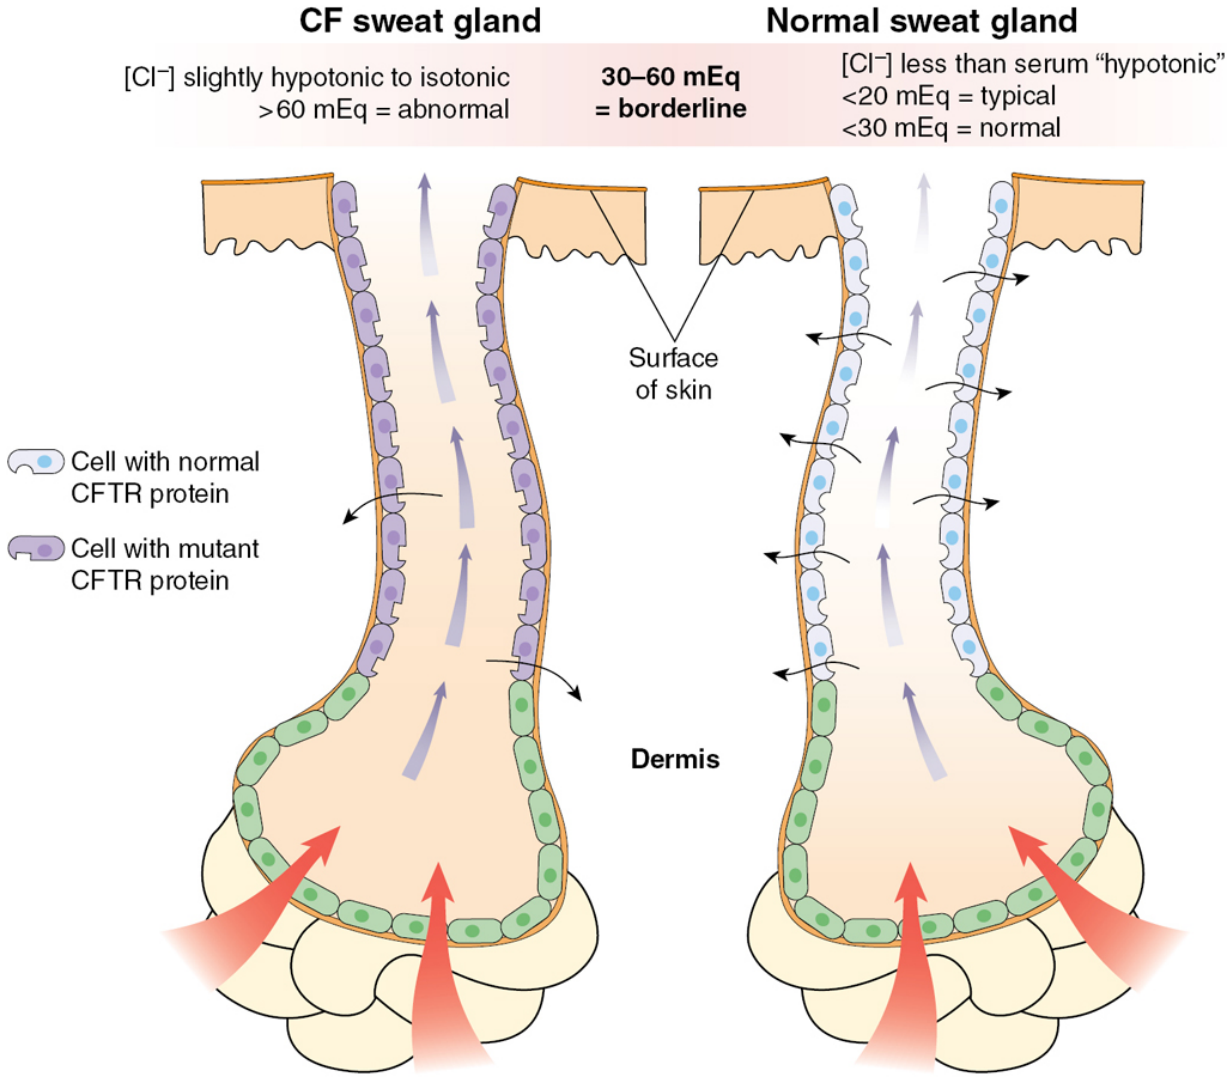

Figure 21-2 Chloride transport in sweat glands of normal and cystic fibrosis individuals. CFTR, cystic fibrosis transmembrane regulator. (Adapted with permission of American Society for Microbiology from Lyczak JB, Cannon CL, Pier GB. Lung infections associated with cystic fibrosis. *Clin Microbiol Rev*. 2002;15(2):194–222; permission conveyed through Copyright Clearance Center, Inc.)

Pancreatic Involvement

The exocrine and ultimately the endocrine functions of the pancreas are affected in CF. Pancreatic enzymes normally are secreted into bicarbonate-rich fluid from the pancreatic duct. The loss of CFTR function inhibits the secretion of digestive enzymes and bicarbonate into the duodenum, resulting in ductal obstruction. With time, these enzymes (lipase, protease, and amylase) accumulate and eventually begin to digest the pancreatic tissue.[5,16] The term *cystic fibrosis* arises from the fibrotic scar tissue that replaces the destroyed pancreas. Without these enzymes, there is poor digestion of fats and, to a lesser extent, proteins and carbohydrates. As a result, 90% of patients with CF experience pancreatic insufficiency characterized by steatorrhea (fatty stools), decreased absorption of the fat-soluble vitamins (A, D, E, and K), malnutrition, and failure to thrive. Early in life, serum concentrations of amylase and lipase are increased secondary to pancreatic autodigestion. This destructive process can result in either painful or asymptomatic chronic pancreatitis.

Eventually, the progressive destruction of the pancreas affects its endocrine function, leading to CF-related diabetes mellitus in 15% to 20% of adolescents and nearly 40% of adults ages 20 to 30 years.[17] The additional diagnosis of diabetes in CF is associated with more rapid decline in lung function and shortened survival. Early aggressive insulin therapy can result in improved clinical outcomes.

Gastrointestinal Involvement

Meconium ileus, an intestinal obstruction at birth, occurring in 20% of newborns with CF, is an inheritable trait of this disease.[18] Outside the neonatal period, distal intestinal obstruction syndrome (DIOS, also called *meconium ileus equivalent*) can occur at any age and results from the complete or partial obstruction of the intestine. Intestinal obstruction occurs in 10% to 20% of patients and results from the inspissation of intestinal secretions and incompletely digested intestinal contents. A right lower quadrant mass, abdominal distension, failure to pass stools, and vomiting can accompany DIOS.

Gastroesophageal reflux disease (GERD) is common in both children and adults with CF.[19–21] Children with CF should be screened for GERD and treated if diagnosed. Other intestinal complications include rectal prolapse, intussusception, and appendiceal abscesses.

Hepatic Involvement

Located on the apical surfaces of the cells lining the intrahepatic and extrahepatic bile ducts and the gallbladder, CFTR functions to facilitate ion transport.[22] In people with CF, the abnormal chloride efflux across the cells results in the reduction in water and sodium movement into the bile. The resulting decrease in the volume and flow of bile leads to stasis and obstruction of the biliary tree. With chronic obstruction, inflammation gives rise to the characteristic lesion of focal biliary cirrhosis.[23]

Liver disease develops in the first decade of life. Significant liver disease is seen in 13% to 25% of children with CF.[24–26] Prevalence rates may be underestimated. Progressive cirrhosis is associated with portal hypertension, hypersplenism, esophageal varices, ascites, and, in a small number of patients, complete hepatic failure requiring transplantation. Approximately 30% of adult patients with CF have abnormal gallbladder function and size (absent or small gallbladder) with 5% to 10% of patients forming gallstones.[27]

Genitourinary Involvement

Approximately 98% of male patients with CF are infertile secondary to in utero obstruction of the vas deferens or related structures. Hormonal secretion and secondary sexual characteristics are normal. In a small number of patients, infertility can be the only manifestation of disease, and CF may go undiagnosed until fertility testing is performed. The prevalence of infertility is higher in females with CF and is hypothesized to be related to the production of thick and tenacious cervical mucus.

Bone and Joint Involvement

Patients with CF have low bone mineral density, slower rate of bone formation, an accelerated rate of bone loss, and arthritis.[28,29] Osteoclastic precursors are elevated during acute pulmonary exacerbation.[30] Although early, aggressive treatment of pulmonary exacerbations can improve bone health, sufficient intake and absorption of the fat-soluble vitamins, D and K, are important, and oral bisphosphonates may also be indicated.[31]

Patients with CF often suffer from intermittent arthritis symptoms, but only about 2% of patients have persistent symptoms. The three types of intermittent CF arthritis are (a) hypertrophic osteoarthropathy, (b) immunoreactive, and (c) CF arthropathy. The first two types are associated with pulmonary disease flare-up. The third type, CF arthropathy, affects large joints and may be accompanied by fever and erythema nodosum.[32–35]

Sinus Involvement

Nasal polyps, which are outgrowths of normal sinus epidermis, can be found in up to 20% of older patients with CF and may become sufficiently large to block nasal passages. The pathogenesis of these polyps is unknown, but the obstruction of nasal passages can lead to infection. The faulty ionic transport of chloride across the apical membrane of epithelial cells lining exocrine glands leads to dehydration of extracellular fluids and the development of thickened inspissated mucus in nasal and sinus passages. Nearly all patients with CF (90%–100% of patients age >8 months) develop sinus disease. On radiographic examination, >90% of adult-age patients have pansinusitis, which can contribute to pulmonary exacerbations.[36,37] The impact of sinusitis on the CF population is significant.

Pulmonary Involvement

Respiratory disease is of major importance in patients with CF because it is the principal cause of repeated hospitalizations, decline in pulmonary function, and death. Although the exact pathophysiologic mechanisms leading from the *CFTR* cellular defect to the development of bronchiectasis and loss of pulmonary function are not completely understood, recent research in animal models and infants with CF has greatly expanded our understanding of this process.[38]

AIRWAY OBSTRUCTION, INFECTION, AND INFLAMMATION

The lower airways of a normal lung are maintained free of pathogens through various lung defense mechanisms. For example, a thin film of liquid on the airway surfaces called the *airway surface layer* (*ASL*) contains antimicrobials, antioxidants, proteases, and other substances that work to eliminate pathogens. In addition, the ASL can remove invading microbes from the lung by moving a mucous gel toward the mouth through ciliary motion. Mucociliary clearance of microbes and debris is aided by the cough reflex to keep the airways clear. Because coughing is an important defense mechanism, cough suppressants should not be used in patients with CF.

In patients with CF, the CFTR defect reduces the ASL, resulting in markedly thickened mucus and impaired mucociliary clearance. Continued mucus hypersecretion leads to mucus plugging and airway obstruction. Additionally, the CFTR defect causes acidification of the ASL secondary to reduced bicarbonate secretion, resulting in reduced host antimicrobial protein activity and increased susceptibility to infection.[39] Hypoxic gradients within the mucus lead to adaptations of *P. aeruginosa* to the anaerobic environment by increasing alginate production and the formation of biofilms. In response to infection, proinflammatory cytokines (eg, tumor necrosis factor-α, interleukin [IL] 1), chemokines (eg, IL-8), and other inflammatory mediators (eg, leukotriene B_4) are released from airway epithelial cells and alveolar macrophages, resulting in neutrophil recruitment into the airways. Recent evidence from infants with CF indicates airway inflammation may precede evidence of infection and

contribute to early lung injury.[40] As the neutrophils undergo apoptosis, they release their DNA, which accumulates and contributes to airway obstruction. In the normal host, proteases (eg, neutrophil elastase) are released in response to an infectious insult and digest the bacteria, while lung tissue is protected by the presence of antiproteases. In patients with CF, the intense neutrophilic infiltration in response to IL-8 results in an imbalance between airway proteases and antiproteases.[41] The excess proteases cause degradation of elastin, a structural component of the airways. In addition, airway proteases can degrade cell-surface receptors (eg, CXCR1 from neutrophils), leading to impaired bactericidal activity contributing to the persistence of *P. aeruginosa* within the airways despite a robust inflammatory response.[42] The chronic cycle of airway obstruction, infection, and inflammation leads to bronchiectasis, progressive loss of lung function with eventual respiratory failure, and death.

MICROBIOLOGY

The microbiology of airways in patients with CF changes as a function of age. In infants and toddlers, the principal organisms include nontypeable *Haemophilus influenzae* and *Staphylococcus aureus.* In older children and adults, *P. aeruginosa* becomes the predominant pathogen (60% of adults). Other pathogens in CF include *Achromobacter xylosoxidans, Aspergillus fumigatus, Burkholderia cepacia, nontuberculous mycobacteria, and Stenotrophomonas maltophilia.*

Pseudomonas aeruginosa

Infections with *P. aeruginosa* occur in three distinct phases. First, the patient acquires the organism and presents with initial infection. Treatment often leads to eradication; however, reinfection eventually occurs and leads to chronic infection. Under pressure from hypoxic gradients within the mucus, *P. aeruginosa* within the airways converts to the mucoid phenotype. Observational studies have noted significant structural as well as functional changes within the lung in

patients with sputum cultures that grow mucoid *P. aeruginosa* when compared with patients with nonmucoid strains or who are not infected with *P. aeruginosa.* Specifically, when compared with patients with nonmucoid *P. aeruginosa,* those with mucoid *P. aeruginosa* had significant abrupt declines in the percentage of predicted forced expiratory volume in 1 second (FEV_1).[43] The median time to acquisition of nonmucoid and mucoid strains is 1 and 13 years, respectively; however, there is tremendous variability in the initial acquisition and development of chronic infection. Patients with delayed acquisition of *P. aeruginosa* typically have minimal lung disease and few hospital admissions when compared with children who acquire *P. aeruginosa* (in particular mucoid *P. aeruginosa*) earlier in life. The relatively long period between nonmucoid and mucoid *P. aeruginosa* offers an opportunity for intervention with pharmacologic therapy (eg, inhaled and/or oral antibiotics) designed to eradicate the organism from the airways. The mucoid strains create a significant therapeutic challenge because they can develop into biofilms. A biofilm is a community of bacteria that adheres to tissues (eg, airway epithelial cells) and secretes a slimy coating (mucoid exopolysaccharide), which protects it from the hostile environment within which it resides. *P. aeruginosa* biofilms create a therapeutic challenge when compared with their planktonic (freely motile) bacterial counterparts because they evade local defense mechanisms, are slow-growing, and can sequester β-lactamase.

Methicillin-resistant *Staphylococcus aureus*

The prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) has increased dramatically in recent years and has been associated with a more rapid decline in pulmonary function and increased mortality.[44,45] A randomized controlled clinical trial of rifampin in combination with trimethoprim-sulfamethoxazole for 21 days was successful in eradicating new-onset MRSA infection in 63% of treated versus 39% of controls. In addition, treatment was associated with significant improvements in lung function and nutritional status.[46]

Burkholderia cepacia

Occasionally, infections involve atypical organisms, including *B. cepacia* (2.8%). *B. cepacia* is actually a complex consisting of several distinct species. *Burkholderia cenocepacia* is the most frequently isolated and clinically relevant species in patients with CF. *B. cepacia* is easily transmitted via inhalation or contact with a reservoir of *B. cepacia,* including other patients with CF, health care professionals, or contaminated medical instruments. Colonization with *B. cepacia* can manifest as chronic asymptomatic carriage, progressive deterioration of lung function, or fatal decline during a short interval often associated with septicemia (known as *B. cepacia* syndrome) and is associated with a 50% reduction in life expectancy.[47] *B. cepacia* is intrinsically resistant to many antibiotics, including aminoglycosides and β-lactams, which limits treatment options. Because of the adverse health outcomes and limited treatment options, chronic infection with *B. cenocepacia* is a relative contraindication to lung transplantation at many centers, emphasizing the importance of preventing the acquisition of this organism through active infection control measures.

Aspergillus fumigatus

Aspergillus species present a unique challenge in patients with CF. The presence of this organism often ignites an immunologic response characterized by an increase in serum immunoglobulin E and eosinophilic infiltration of the alveoli. This syndrome is referred to as allergic bronchopulmonary aspergillosis (ABPA). The typical symptoms of this syndrome include wheezing, shortness of breath, low-grade fever, and production of thick, brownish, or bloody sputum. This disease is not invasive; however, chronic eosinophilic infiltration can lead to bronchiectasis and lung scarring. ABPA is present in ~10% of patients with CF and accounts for 10% of acute pulmonary exacerbations. The diagnosis of ABPA can be challenging owing to the overlap in clinical features with acute pulmonary exacerbations. A consensus conference sponsored by the Cystic Fibrosis Foundation (CFF) provides guidelines for the diagnosis and

treatment of ABPA in patients with CF.[48] The minimal diagnostic criteria include clinical deterioration, elevated total serum immunoglobulin E (>500 international units/mL), positive immediate *A. fumigatus* skin test or serum immunoglobulin E antibodies, and *A. fumigatus* serum precipitins or immunoglobulin G antibodies or radiographic changes. Annual screening of serum immunoglobulin E concentrations is recommended for patients with CF age 6 years or older. Treatment of ABPA includes oral corticosteroids and azole antifungals.

DIAGNOSIS

The diagnosis of CF can be made soon after birth through newborn screening or later in life based on the presentation of symptoms. A newborn screening test based on the measurement of trypsinogen concentrations in blood is performed for early diagnosis of CF. Trypsinogen is normally produced in the pancreas and is carried to the small intestine, where it changes from an inactive proenzyme to the active enzyme trypsin, which is used in the digestion of proteins. In infants with CF, mucus can block the ducts from the pancreas into the small intestine. The mucus prevents trypsinogen from reaching the intestines, resulting in accumulation in the blood. This process can be detected and measured because immunoreactive trypsin (IRT) levels increase in the blood of the infant. The IRT testing is a screening test; confirmatory testing including a sweat chloride test and DNA analysis for CF mutations should be performed in infants with a positive IRT.[49]

When the pilocarpine iontophoresis test (ie, sweat chloride test) is conducted at a certified CF center and is positive (≥60 mM), the diagnosis of CF can be applied, a value of 40 to 59 mM indicates possible CF and should be repeated in conjunction with DNA analysis.

DNA analysis is recommended and is expected to identify 90% of CFTR mutations. The DNA analysis used for population screening is

not as sensitive at detecting CFTR mutations in non-White populations. Prenatal screening for the presence of a CF carrier state in the parents is recommended by the American College of Medical Genetics and the American College of Obstetrics and Gynecology.[50]

Symptoms Suggestive of Cystic Fibrosis

For those in whom CF may not have been detected by newborn screening, the suspicion for CF is raised by clinical symptoms. Infants born with meconium ileus, an intestinal obstruction attributable to thickened meconium, at birth are highly likely to have CF. Other clinical symptoms that require further diagnostic testing are listed in **Table 21-2**. Presence of these symptoms warrants obtaining a sweat chloride and DNA analysis.

Table 21-2
Phenotypic Features Consistent With Diagnosis of Cystic Fibrosis

Persistent colonization or infection with typical CF pathogens (eg, *Staphylococcus aureus,* nontypeable *Haemophilus influenzae, Pseudomonas aeruginosa,* and *Burkholderia cepacia*)
Chronic cough and sputum production
Persistent chest radiograph abnormalities
Airway obstruction manifested by wheezing and air trapping
Nasal polyps; radiographic or computed tomographic abnormalities of paranasal sinuses
Digital clubbing
Meconium ileus, distal intestinal obstruction syndrome, and rectal prolapse
Pancreatic insufficiency and recurrent pancreatitis
Chronic hepatic disease
Failure to thrive, hypoproteinemia and edema, and complications secondary to fat-soluble vitamin deficiency
Salt loss syndromes: acute salt depletion and chronic metabolic alkalosis

Male urogenital abnormalities resulting in obstructive azoospermia (CBAVD)

CBAVD, congenital bilateral absence of the vas deferens.

CASE 21-1

QUESTION 1: K.M. is a 1-week-old girl weighing 6.39 pounds (2.9 kg) who presents for routine follow-up. Her birth weight was 5.95 pounds (2.7 kg). She is growing well on breast milk every 3 hours. Areview of systems reveals no abnormalities. K.M.'s newborn screening panel has returned with an elevated IRT concentration.

What further testing is recommended to determine whether this infant has CF?

At this time, it is recommended that K.M. have a sweat chloride test and DNA analysis performed. If K.M. has a positive sweat chloride, additional testing is recommended to determine whether she has pancreatic insufficiency. The preferred testing method is fecal elastase, which is measured in a single stool sample. Fecal elastase is not degraded during intestinal transit and has been shown to correlate well with duodenal lipase, amylase, trypsin, and bicarbonate concentrations. A low value indicates the presence of pancreatic insufficiency necessitating enzyme supplementation. Although 25% of infants with CF are pancreatic sufficient at the time of diagnosis, most will become pancreatic insufficient in the first year of life.[49] For those age 8 years or older, a serum trypsinogen may be used to assess pancreatic function.

EARLY INTERVENTIONS AND THERAPY

CASE 21-1, QUESTION 2: K.M. returns to the clinic 2 weeks later. Testing has revealed a sweat chloride of 84 mM and the presence of homozygous F508del

mutations. Fecal elastase is low, and the diagnosis of pancreatic insufficiency is made. What therapy should be initiated at this time?

K.M. now meets the diagnostic criteria for CF with pancreatic insufficiency. Early nutritional therapy to ensure appropriate growth is essential as good nutritional status has been associated with improved pulmonary outcomes.[51] Patients with CF are hypermetabolic and do not absorb fats and proteins normally. Therefore, the CF diet must be high in calories, fat, and protein. It is recommended that those with CF have an energy intake of 110% to 200% of that recommended for the general population.[52] If K.M. has difficulty gaining weight, the frequency of breastfeeding may need to increase or she will need to be changed to high-calorie infant formula.

Vitamin and Mineral Supplementation

The malabsorption of fats in patients with CF with pancreatic insufficiency also results in decreased gastrointestinal absorption of the fat-soluble vitamins (A, D, E, and K). Approximately 45% of the CF population is deficient in one of these vitamins, even when pancreatic enzymes are being used appropriately.[53] The current recommendations for replacement therapy are listed in **Table 21-3**.[54] Concerns about inadequate supplementation of vitamins D and K resulting in poor bone health have arisen.[55,56] Calcium supplementation will be needed for those receiving inadequate calcium in their diet. Iron supplements might also be needed if iron-deficiency anemia occurs.

Table 21-3

Daily Recommended Doses of Fat-Soluble Vitamins for Patients With Cystic Fibrosis and Vitamin Content in Specialty Vitamin Formulations

Age	Vitamin A[a] (μg)	Vitamin E[b] (mg)	Vitamin D[c] (μg)	Vitamin K (mg)
0–12 months	450	27–33.6	10–12.5	0.3–0.5
1–3 years	1500	54–100	20–25	0.3–0.5

[a]1 international unit = 0.3 μg

[b]1 international unit = 0.67 mg

[c]1 international unit = 0.025 μg

K.M. should be started on a CF-specific liquid multivitamin preparation. Additional vitamins may be supplemented if laboratory monitoring reveals an abnormality. Additionally, K.M. should receive 1/8 teaspoon of table salt per day to account for sodium loss in sweat.[57] At age 6 months, the dose increases to 1/4 teaspoon. For bottle-fed infants, a small amount of salt is added to each feeding. For K.M., who is breastfed, the parents should attempt pumping and bottle-feeding with breast milk twice a day to add salt. If K.M. does not tolerate bottle-feeding, the salt is not supplemented, and they should ensure K.M. is not exposed to warm conditions for a prolonged time.

Enzyme Supplementation

The mainstay of treatment for pancreatic insufficiency is the exogenous replacement of pancreatic digestive enzymes. The goals of pancreatic enzyme supplementation are to (a) improve weight

gain, (b) minimize steatorrhea, and (c) eliminate abdominal cramping and bloating. Supplementation with currently available therapies does not fully restore fat absorption, and the absorption of sufficient fat-soluble vitamins continues to be problematic.[58] The digestive enzymes (lipase, protease, and amylase) are available in a mixture of approximately one part lipase to three parts protease and three parts amylase in capsules that contain enteric-coated microspheres of these enzymes. The enteric coating protects these enzymes from gastric acid. Because the breakdown of fat is the most important function of these enzymes, dosing is based on the lipase content, and the dose varies according to weight, age, dietary fat intake, and symptom severity. The initial dose for infants is 2000 to 5000 units of lipase per breastfeeding or per 120 mL of bottle-feeding. Infants eating solid food begin at a dose of 1000 units/kg/meal.[57] For children age >4 years, 500 units of lipase/kg/meal is the initial dose for enzyme supplementation.[52] A full dose is taken with meals, and half the prescribed dose is taken with snacks. Subsequent dosing adjustments are titrated to response. Lack of weight gain, smelly, greasy stools, and abdominal pain or bloating might be indicative of insufficient enzyme supplementation.[59,60]

High-strength pancreatic enzymes have been associated with colonic strictures, which are accompanied by symptoms similar to that of DIOS. Although cause and effect have not been firmly established, doses >6500 units of lipase/kg/meal have been associated with stricture formation. As a result, most recommend that the daily dose of lipase not exceed 10,000 units of lipase/kg or 2500 units of lipase/kg/meal.[52]

When patients require unusually high doses of enzyme supplements, it sometimes can be attributable to high gastric acidity. The enteric coating on the pancreatic enzyme microspheres dissolves at a pH of 5.8, and the enzymes are destroyed at a pH of 4.0. Patients with CF have longer postprandial periods when the pH is <4.0 in the bowel and also have significantly less time when the pH is >5.8. Because enzymes may be less effective when the bowel pH is very low,[61,62] adding a histamine type H_2 antagonist or a

proton-pump inhibitor to increase gastric pH might help lower the enzyme dosing requirement.[63–65]

K.M. should receive a pancreatic enzyme supplement of 2000 to 5000 units per feeding. Although K.M. is not yet eating solid food, the capsule may be opened and the contents sprinkled on a small amount (eg, a baby's spoonful) of rice cereal, baby food, or applesauce and given before each feeding. K.M.'s caregivers should ensure that no beads are left in her mouth after the feeding is complete.

Pulmonary Interventions

Although data on the benefits of airway clearance and bronchodilator therapy in infants are sparse, these interventions are recommended by the CFF.[57] Generally, albuterol may be administered before percussion and postural drainage (P&PD; see Treatment of Cystic Fibrosis Airway Disease: Mechanical Methods section) once daily in infants with CF. The frequency of treatments may be increased if symptoms become evident. Respiratory syncytial virus affects most infants and may more adversely affect those with CF. Therefore, palivizumab is recommended in those with CF age 2 years or younger.[57] K.M. should receive albuterol by nebulizer or metered-dose inhaler and spacer once daily before airway clearance. She should also receive palivizumab 15 mg/kg intramuscularly once a month during respiratory syncytial virus season.

Case 21-1, Question 3: What monitoring is recommended for K.M.?

K.M.'s head circumference, height, and weight should be plotted on standard growth charts every month for the first year. The goal is for her to have a weight-for-length status of the 50th percentile.[52] After the first year, quarterly growth evaluations are recommended. From ages 2 to 20 years, the goal for growth is to achieve at least the 50th percentile for body mass index (BMI). An experienced, knowledgeable registered dietitian should meet with the family to

help them understand the importance of appropriate nutrition and help develop a plan for K.M. Fasting blood glucose, liver function tests, albumin, serum electrolytes, complete blood count, prothrombin time, and vitamins A, D, and E levels should be determined now, at age 1 year, and at least annually. An abdominal examination should be done to determine liver and spleen size and consistency at each office visit.

Pulmonary status is monitored based on clinical symptoms, auscultation of the chest, and chest radiographs until about age 5 years, when pulmonary function testing may be performed. Oropharyngeal cultures are recommended at least quarterly to detect the presence of pathogenic bacteria.

Those with CF are at risk for CF-related diabetes, warranting annual oral glucose tolerance testing (OGTT) starting at age 10 years.[17] They are also at increased risk for osteoporosis and should be assessed annually for risk factors. Bone densitometry is recommended for all adults and starting at age 8 years in those with risk factors including low vitamin D, FEV_1 <50%, oral corticosteroid use >90 days in a year, diabetes, delayed puberty, and BMI <25th percentile.[66] K.M. currently does not have any known risk factors for osteoporosis and is too young for bone densitometry. Her risk should be reevaluated annually starting at age 8 years.

Treatment of Cystic Fibrosis Airway Disease

In addition to CFTR, modulator therapies are directed against the basic defect (see Cystic fibrosis transmembrane regulator modulator therapy section below), treatment of CF airway disease involves the use of medications and techniques to mobilize pulmonary secretions, antibiotics to manage infection, and anti-inflammatory agents to reduce airway inflammation.[67]

MUCOCILIARY CLEARANCE

Sputum in patients with CF is difficult to mobilize because pulmonary secretions are thick as a result of the CFTR defect, the large

amounts of viscous DNA from the breakdown of white blood cells, and the bacterial debris left over from chronic infections. Mechanical clearance methods, inhaled mucolytics, and airway hydration therapies can help mobilize pulmonary secretions.

Mechanical methods

Methods used to mechanically break up and mobilize mucus in the pulmonary tree include traditional hand P&PD, oscillating positive-end pressure (OPEP) with the flutter valve, high-frequency chest-wall oscillation (HFCWO), intrapulmonary percussive ventilation, and autogenic drainage (a technique of deep-breathing exercises).

See **https://www.cff.org/Life-With-CF/Treatments-and-Therapies/Airway-Clearance/Airway-Clearance-Techniques/.**

These mechanical approaches for mobilizing mucus are about equal in efficacy, and the selection of the most appropriate one for a patient depends on the ability, motivation, preference, and resources of the patient.[68] When the traditional P&PD was compared with HFCWO and OPEP, clinical efficacy and safety were comparable, but 50% of patients preferred the HFCWO, 37% preferred OPEP, and 13% preferred P&PD.[69]

Dornase alfa

Dornase alfa is an inhaled recombinant form of human deoxyribonuclease I, which breaks up the extracellular DNA formed by apoptotic neutrophils that contributes to airway obstruction in patients with CF. The pivotal clinical trial demonstrated improvement in pulmonary function (FEV_1 5.8% vs placebo, $P < .01$) and a reduction in exacerbation frequency (28% vs placebo, $P = .04$) in patients receiving dornase alfa.[70] Based on these benefits, the use of dornase alfa is recommended in all patients age 5 years or older.[67] Consideration can be given to treating infants and toddlers as well if

their clinical symptoms support the presence of airway disease. Dornase alfa is expensive, with costs averaging about $3600/month, and the cost–benefit ratio for its use continues to be debated.[71,72] A reasonable approach is to provide a brief trial of dornase alfa (1–2 months) to determine whether there is improvement in pulmonary function, and the medication is well tolerated. A longer trial (up to 1 year) may be necessary to assess its effect on the hospitalization rate.

Dornase alfa is available in 2.5 mg vials and is administered once daily via a vented jet nebulizer or eRapid™ nebulizer system. The drug must be stored in the refrigerator and protected from light. Patients should be instructed on the proper use and maintenance of the nebulizer and compressor system. In addition, patients should be instructed not to dilute or mix dornase alfa with other drugs in the nebulizer.

Airway hydration therapies

Hypertonic Saline

Inhalation of hypertonic saline (IHS) improves mucociliary clearance.[73] Hypertonic saline rehydrates the airways through osmotic flow of water. When twice-daily inhaled normal saline was compared with 7% (hypertonic) sodium chloride, no difference was noted in the primary outcome, which was the linear rate of pulmonary function decline during the 48-week study period.[74] However, patients randomly assigned to receive IHS experienced a significant reduction in exacerbations (56% decrease vs placebo, P = .02). In two small, randomized, crossover trials, dornase alfa provided a greater improvement in lung function, albeit at a much higher financial cost than IHS ($70/month). One approach is to consider the use of IHS in patients who are intolerant or do not respond to a trial of dornase alfa. In addition, IHS should be considered as add-on therapy in patients with airway congestion despite optimal standard therapy (ie, dornase alfa and chest physiotherapy). A short-acting β_2-agonist should be given before IHS treatment because IHS has been associated with bronchospasm.[75]

IHS is available commercially, and its use is recommended to improve lung function and reduce exacerbations in all patients age 6 years or older.[67] Recent data on the efficacy of IHS in infants during the first month of life demonstrate improved lung clearance index and weight.[76]

Inhaled Mannitol

The dry powder formulation of mannitol is an inhaled hyperosmotic agent designed to increase mucus clearance. To date, a total of 784 people with CF have been enrolled to assess the safety and efficacy of inhaled mannitol.[77] Overall, results showed a small but statistically significant improvement in lung function in treated patients when compared with a placebo. The rates of pulmonary exacerbations in patients receiving inhaled mannitol were not significantly different than placebo.

Considering the modest improvement in lung function and lack of effect on pulmonary exacerbation frequency, the use of inhaled mannitol may be considered in patients who are intolerant of inhaled hypertonic saline.

The dose is 400 mg of mannitol, administered through oral inhalation of ten 40-mg hard gelatin capsules twice daily using the inhaler. Each inhaler is used for 1 week and is then discarded. Prior to treatment initiation, patients are required to undergo a tolerance test to evaluate if the treatment will cause bronchospasm.

Bronchodilation

The chronic use of inhaled β_2-agonists improves lung function in patients with bronchial hyperresponsiveness or a positive bronchodilator response and is recommended for use.[67] In addition, they may assist in airway clearance when administered before chest physiotherapy. No clear consensus exists for the use of other bronchodilators. Studies in support of inhaled anticholinergic medications for the treatment of CF also are limited, and the results have been mixed.[78]

Cystic fibrosis transmembrane regulator modulator therapy

The role of CFTR modulation is rapidly evolving and significantly impacting the quality of life and clinical outcomes for people with CF. There are currently four molecular entities utilized in various combinations and for specific CF genotypes; ivacaftor, lumacaftor, tezacaftor, and elexacaftor. Ivacaftor, a *CFTR* potentiator, improves chloride transport at the cell surface and is used in people age 4 months or older, with at least one gating (class III) or residual function (class IV or class V) defect. Ivacaftor is considered a highly effective therapy owing to the magnitude of response seen in clinical trials. A phase 3 trial in people with at least one copy of a *G551D* mutation demonstrated improvements in pulmonary function (absolute change of 10% in FEV_1), and a 55% reduction in risk for acute pulmonary exacerbations over the 48-week study period.[79]

Ivacaftor is a substrate for CYP3A and coadministration with moderate or strong inducers is not recommended. In addition, dosage adjustment is necessary when coadministered with moderate or strong inhibitors of CYP3A or when used in patients with moderate or severe hepatic disease. Monitoring of liver function tests as well as ophthalmologic examinations for potential lens opacities is recommended for all drug regimens that include ivacaftor.

Lumacaftor is a *CFTR* corrector, correcting misfolded CFTR protein so that it can be presented to the cell surface. However, that corrected CFTR protein is not fully functional without adding a *CFTR* potentiator. The combination product containing lumacaftor and ivacaftor is recommended starting at age 2 for people homozygous for the *F508del* mutation. Lumacaftor/ivacaftor has a modest effect on CF outcomes. A phase 3 study evaluating the combination of lumacaftor/ivacaftor in patients homozygous for the *F508del* mutation demonstrated some improvement in pulmonary function (absolute improvement in FEV_1 of 2.6%–4%) and a 30% to 39% reduction in the rate of pulmonary exacerbations.[80]

Tezacaftor is also a *CFTR* corrector that, when combined with ivacaftor, has a modest effect on CF outcomes. Tezacaftor/ivacaftor

combination therapy is recommended for people age 6 years or older, who are homozygous for the *F508del* mutation, and those with one *F508del* and a residual function mutation (class IV or class V). Phase 3 studies demonstrated a 6.8% absolute improvement in FEV_1 compared to placebo and a 35% reduction in the rate of pulmonary exacerbations for both the homozygous and heterozygous groups.[81,82]

Elexacaftor is also a *CFTR* corrector with a different binding site than that of tezacaftor. When combined with tezacaftor and ivacaftor, it is considered a highly effective modulator therapy. The triple combination of elexacaftor/tezacaftor/ivacaftor is recommended for people age 6 years or older with at least one *F508del* mutation. This inclusion of all people heterozygous for *F508del*, regardless of the second genotype, has made a therapy available to a larger population of people with CF, many of who were not candidates for previous *CFTR* modulator therapies. A phase 3 study comparing elexacaftor/tezacaftor/ivacaftor for people homozygous for the *F508del* mutation demonstrated a 10% absolute improvement in FEV_1 for triple therapy compared to tezacaftor/ivacaftor.[83] For people heterozygous for the *F508del* mutation who did not previously qualify for *CFTR* modulator therapy, a phase 3 study demonstrated a 13.8% absolute improvement in FEV_1 compared to placebo and a 63% reduction in pulmonary exacerbations.[84] This triple combination therapy is now approved for children aged 6 years and older by the Food and Drug Administration (FDA).

Starting *CFTR* modulator therapy early in life is anticipated to significantly impact long-term survival. Based on K.M.'s CF mutations, she will qualify for lumacaftor/ivacaftor therapy once she is 2 years old. Lumacaftor/ivacaftor is available as a granule formulation allowing for administration to young children.

CASE 21-2

Question 1: J.P. is a 12-year-old girl who was seen for a routine quarterly visit at the CF center. J.P. was diagnosed with CF at age 2 months as a result of newborn screening. Genotyping revealed she is homozygous for *F508del*. At

this visit, she has increased cough and chest congestion when compared with her visit 3 months ago. She has a history of hemoptysis but has not had an episode recently. She has had no pulmonary exacerbations in the last 12 months. Her current medications include pancreatic enzymes (~2000 units of lipase/kg/meal) with all meals, a fat-soluble vitamin supplement, two puffs of albuterol inhaler before airway clearance treatment once daily, tezacaftor 100 mg/ivacaftor 150 mg in the morning and ivacaftor 150 mg at night, dornase alfa 2.5 mg via nebulization once daily, and fluticasone 44 µg inhaler two puffs daily. She performs airway clearance using HFCWO for 30 minutes once daily and reports she is tolerating this therapy well. Microbiological cultures of her oropharyngeal tract grow *S. aureus*; she has not grown *P. aeruginosa* in the past. J.P.'s BMI is in the 60th percentile (stable from the last visit), and her lung function tests show an FEV_1 of 1.99 L (89% predicted), which is down from her baseline of 2.05 L (92% predicted). A recent chest computed tomography revealed mild bronchiectatic changes in all lobes as well as mucus plugging and air trapping.

What steps should be taken to improve J.P.'s airway clearance?

Methods of mechanical assistance to remove pulmonary secretions are all equally effective, and the decision about which device to use should be individualized. J.P. is currently using HFCWO and appears to be tolerating this well. One advantage to this treatment is the independence it provides when compared with manual percussion and drainage, which requires the assistance of another individual. It also is efficient as the patient can perform some nebulization treatments while on the therapy vest (eg, hypertonic saline).[67] This is an especially important consideration to improve adherence. The typical frequency and duration of treatment with HFCWO is 30 minutes twice daily. J.P. is currently using the therapy vest only once daily and could benefit from increasing the frequency of treatment to twice daily.

Dornase alfa improves sputum viscosity in patients with CF and provides benefits early during lung disease.[85] In the Pulmozyme Early Intervention Trial, the risk of pulmonary exacerbations was reduced by 34% in young patients with mild lung function abnormalities, and pulmonary function tests improved even in patients with close to normal pulmonary function. J.P. is currently receiving dornase alfa and should continue this therapy to improve pulmonary function and reduce the risk of pulmonary exacerbations.

Hypertonic saline (7%) twice daily should also be considered for J.P. to enhance the mucociliary clearance and improve pulmonary function. The albuterol should be increased to twice daily to provide bronchodilation to prevent potential bronchospasm from the hypertonic saline. The recommended sequence of the treatments is albuterol for bronchodilation, hypertonic saline to hydrate the airways, and dornase alfa to liquefy the mucus, followed by airway clearance therapy to clear the mucus.[67] If adherence is an issue, the hypertonic saline can be administered during airway clearance treatment.

Based on her age, J.P. can be changed to triple *CFTR* modulator therapy with elexacaftor/tezacaftor/ivacaftor. Because triple therapy is considered highly effective compared with other therapies, it is recommended to make this change. J.P. should be counseled on the potential to have increased mucus productivity during the first few days of therapy. Once changed, the liver function will need to be monitored every 3 months for the first year of therapy. Additional common adverse effects may include rash, gastrointestinal upset, and headache. Many patients experience an increase in appetite which is typically desired, but in some cases may lead to excess weight gain.

Control of Inflammation

The inflammatory response in CF airways contributes significantly to the destruction of the airways and eventual pulmonary function decline. Pharmacologic intervention to block the intense neutrophilic inflammatory response is a key strategy to reducing pulmonary disease progression. Corticosteroids, nonsteroidal anti-inflammatory drugs, and macrolides have all been used to control the inflammation seen in CF lung disease. Although leukotriene modifiers have improved lung function in small studies, the overall data are insufficient to support a recommendation for their use.[86] Cromolyn use also is not routinely recommended because of limited evidence of positive outcomes with this drug.[67]

CASE 21-2, QUESTION 2: Is J.P. a candidate for anti-inflammatory therapy?

CORTICOSTEROIDS

Oral corticosteroids are not recommended in the treatment of CF. Although prednisone 1 to 2 mg/kg every other day demonstrated a significant reduction in the decline of lung function and decreased pulmonary exacerbations in patients with *Pseudomonas* infections, long-term use was associated with unacceptable adverse effects including cataracts, glucose intolerance, osteoporosis, and persistent growth retardation.[87–89] Although inhaled corticosteroids are widely prescribed to patients with CF, there are limited data supporting their use in this population. In particular, a randomized controlled trial of withdrawal of inhaled corticosteroids demonstrated no change in pulmonary function after discontinuation; therefore, they are not recommended for routine use in patients with CF in the absence of concomitant asthma.[67,90] Fluticasone should be discontinued in J.P., and pulmonary function testing should be performed at the next clinic visit. In addition, J.P. should be questioned about wheezing or shortness of breath.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonsteroidal anti-inflammatory drugs have been used to slow lung function decline. High-dose ibuprofen (20–30 mg/kg twice daily with doses titrated to a peak concentration of 50–100 mg/L) can significantly slow the annual rate of FEV_1 decline in children ages 5 to 13 years.[91] Ibuprofen serum concentrations must be measured and monitored closely to stay in the therapeutic range because lower concentrations can paradoxically increase neutrophil infiltration. Because these doses are much higher than the recommended doses to treat pain or fever, concerns about long-term side effects, including gastrointestinal bleeding and renal toxicity, together with the need for frequent blood draws have not made this method of treatment common. For patients age 6 years or older with an FEV_1 >60% of predicted, chronic oral ibuprofen is recommended to reduce

the loss of lung function.[67] Considering J.P.'s history of hemoptysis, the use of high-dose ibuprofen is not recommended.

AZITHROMYCIN

Azithromycin is an antibiotic with anti-inflammatory properties. Although its use is established in patients with CF with chronic *P. aeruginosa* infection (see Case 21-3, Question 3), a study conducted in children and young adults who were not infected with *P. aeruginosa* demonstrated a significant reduction in exacerbation frequency (50%) and increased weight (1.27 pounds [0.58 kg]) during the 24-week study period; however, no improvement in pulmonary function was noted.[92]

Because J.P. has not experienced any pulmonary exacerbations during the past year, there would be little advantage to adding azithromycin unless she becomes infected with *P. aeruginosa*.[67]

ANTIBIOTIC THERAPY

Treatment of pulmonary infections in patients with CF has undoubtedly contributed to the improved survival observed in patients with CF in the past 30 years. Antibiotics are indicated in patients with CF for (a) early eradication of *P. aeruginosa* at the time of the first detection with the intent to prevent or delay chronic infection, (b) treatment of acute pulmonary exacerbations, and (c) chronic maintenance therapy with inhaled antibiotics to control the bacterial burden within the airways to slow the progression of pulmonary function decline.

Early eradication of *Pseudomonas aeruginosa*

CASE 21-2, QUESTION 3: J.P. returns to the clinic 6 weeks later for a follow-up visit to evaluate response to changes made at the previous visit. Subjectively, she reports less chest congestion and cough. Spirometry demonstrates her FEV_1 has returned to baseline. A throat culture is obtained and reveals *P. aeruginosa*. What additional therapies should be considered for J.P. at this time?

Because of the increased rate of pulmonary function decline and shortened survival in patients chronically infected with *P. aeruginosa*, early treatment with the goal of eradication is recommended.[67] Results of two studies guide the optimal treatment approach. The Early Inhaled Tobramycin for Eradication trial demonstrated that treatment with inhaled tobramycin 300 mg twice daily for 28 or 56 days was similar in terms of eradication at 1 month (93% vs 92%) and time to recurrence of *P. aeruginosa* (66% vs 69% culture-free at 27 months).[93] The Early *Pseudomonas* Infection Control trial demonstrated that therapy (inhaled tobramycin 300 mg twice daily for 28 days with or without ciprofloxacin twice daily for 14 days) initiated when quarterly respiratory cultures are positive for *P. aeruginosa* was not different in eradication or recurrence when compared with a similar antibiotic regimen cycled for 28 days followed by 56 days off for a period of six quarterly cycles.[94] Alternatively, results from a recent study conducted with aerosolized aztreonam 75 mg three times daily for 28 days in children age older than 6 years with CF demonstrated eradication in 89.1% at the end of treatment and 58.2% remained culture negative at 28 weeks.[95] A recent study evaluated oral azithromycin 10 mg/kg up to 500 mg three times weekly in combination with inhaled tobramycin for eradication of *P. aeruginosa* in children with CF.[96] The risk of an acute pulmonary exacerbation was reduced by 44% in patients receiving azithromycin in addition to inhaled tobramycin. Based on the results of these two studies, it would be appropriate to start J.P. on inhaled tobramycin 300 mg twice daily (or aztreonam 75 mg three times daily) in combination with oral azithromycin for 28 days. Cultures should be obtained on completion of the therapy to confirm eradication and quarterly thereafter to monitor for recurrence of *P. aeruginosa.*

Acute Pulmonary Exacerbation

Acute pulmonary exacerbations are an inevitable consequence of pulmonary disease in most patients with CF. A pulmonary

exacerbation is defined as a change in respiratory signs and symptoms from the patient's baseline that necessitates treatment with antibiotics and augmented airway clearance. Key indicators include increased cough or sputum production, decreased exercise tolerance, loss of weight or appetite, decrease in FEV_1 or forced vital capacity (FVC) by more than 10%, or onset of new or increased crackles.[97] Approximately one-third of patients experience at least one pulmonary exacerbation annually; however, the onset and frequency vary widely in the population. The frequency of exacerbations is correlated with the severity of the pulmonary disease. Traditional management for an acute CF exacerbation includes nutritional repletion, antibiotics, and chest physiotherapy.[98] For mild exacerbations, the patient can typically be managed in the outpatient setting using oral antibiotics and intensification of airway clearance and nutritional therapies. For moderate-to-severe exacerbations, patients are typically hospitalized and receive a 14-day course of intravenous (IV) antibiotics, as well as airway clearance and nutrition therapies. If the patient demonstrates a significant improvement in signs and symptoms, he or she may be a candidate to complete treatment at home before completion of the 14-day course.[99]

ANTIBIOTIC DRUG SELECTION

Antibiotic drug selection is based on sputum or throat culture and susceptibility data. Combination therapy with two antibiotics with different mechanisms of action is often prescribed for treating acute pulmonary exacerbations involving *P. aeruginosa* to prevent the development of resistance and provide potential synergistic activity. Therefore, the combination of an antipseudomonal β-lactam and an aminoglycoside or fluoroquinolone is frequently used. Results of a controlled trial comparing β-lactam monotherapy versus β-lactam plus an aminoglycoside demonstrated similar improvement in pulmonary function, but a greater reduction in bacterial density in sputum and a longer duration before readmission for a new pulmonary exacerbation in the patients receiving combination

therapy.[100] Multidrug-resistant (MDR) strains, defined as resistance to all agents within two of the three major classes of antipseudomonal therapies (eg, β-lactams, aminoglycosides, and fluoroquinolones), are reported in 15% to 20% of patients. The recent availability of ceftolozane–tazobactam and ceftazidime–avibactam provide new treatment options for infections involving MDR *P. aeruginosa*.

ANTIBIOTIC DOSING

The antibiotics used most commonly to treat acute pulmonary exacerbations and their dosage ranges are listed in **Table 21-4**. Typical dosage regimens used in other populations may not be adequate in patients with CF owing to reduced lung penetration, decreased activity in sputum, presence of bacteria within biofilms, heavy inocula, and reduced susceptibility. Altered pharmacokinetics of drugs in patients with CF is also frequently cited in the published literature. In particular, both the volume of distribution and clearance of a number of antibiotics (eg, β-lactams and aminoglycosides) are reported to be higher in patients with CF when compared with healthy control subjects. One potential explanation for the observed differences in pharmacokinetics in CF is related to differences in body composition. Patients with CF have reduced adipose tissue and lean mass owing to nutritional deficiencies. If the pharmacokinetic parameters are normalized to body weight (eg, L/kg and L/kg/hour), then the parameters would appear to exceed that of normal healthy individuals. This observation was recently demonstrated in a clinical trial evaluating the pharmacokinetics of ceftazidime in CF. The intersubject variability in pharmacokinetic parameters was significantly reduced when the parameters were normalized to fat-free mass, indicating that fat-free mass is a better metric for normalization.[101] Importantly, the authors observed that the pharmacokinetic parameters appeared higher when normalized to body weight; however, when normalized to fat-free mass, there was no significant difference.

Table 21-4
Antibiotic Doses for Cystic Fibrosis

Systemic Antibiotics			
Drug	**Pediatric Dose**	**Adult dose**	**Maximum daily dose**
Amikacin	30 mg/kg q24h	30 mg/kg q24h	TDM
Aztreonam	150 mg/kg/day divided q6–8h	2 g q6h	12 g/day
Cefepime	150 mg/kg/day divided q6–8h	2 g q6h	8 g/day
Ceftazidime	150–300 mg/kg/day divided q6–8h	2 g q6h	12 g/day
Ceftazidime–avibactam	50 mg/kg–12.5 mg/kg q8h	2.5 g infused over 2h q8h	6 g/day (ceftazidime)
Ceftolozane–tazobactam	30–40 mg/kg q8h	3 g q8h	12 g/day
Ciprofloxacin IV	30 mg/kg divided q8h	400 mg q8h	1.2 g/day
Ciprofloxacin PO	40 mg/kg divided q8–12h	750 mg q8–12h	2.25 g/day
Colistimethate	2.5–5 mg/kg/day divided q8h	2.5–5 mg/kg/day divided q8h	300 mg/day colistin base
Gentamicin	10 mg/kg q24h	10 mg/kg q24h	TDM
Imipenem	100 mg/kg/day divided q6h	1 g q6h	4 g/day
Linezolid	10 mg/kg q8h	600 mg q8–12h	600 mg q8h
Meropenem	60–120 mg/kg/day divided q8h	2 g q8h	6 g/day
Piperacillin–tazobactam	400 mg/kg/day divided q6h	4.5 g q6h	16 g/day (piperacillin)
Ticarcillin/clavulanate	400 mg/kg/day divided q6h	3.1 g q6h	18.6 g/day (ticarcillin)
Tobramycin	10 mg/kg q24h	10 mg/kg q24h	TDM
TMP/SMZ	15–20 mg/kg/day divided q8h	15–20 mg/kg/day divided q8h	800 mg/day
Vancomycin	15–20 mg/kg q6h	15–20 mg/kg q8–12h	TDM
Inhaled Antibiotics			
Drug	**Dosage (mg)**	**Interval**	**Comments**
Aztreonam	75	tid	28 days on, 28 days off
Tobramycin nebulized	300	bid	28 days on, 28 days off
Tobramycin Podhaler	112 (four 28-mg capsules)	bid	28 days on, 28 days off
Colistin	37.5–75	bid	28 days on, 28 days off

bid, twice daily; TDM, therapeutic drug monitoring (gentamicin/tobramycin desired maximal concentration is 25–35 mg/L, AUC_{24h} = 70–100 mg/L × h; once-daily dosing); tid, three times daily; TMP/SMZ, trimethoprim/sulfamethoxazole.

Adapted from Zobell JT, Young DC, Waters C, et al. Optimization of anti-pseudomonal antibiotics for cystic fibrosis pulmonary exacerbations: VI. Executive summary. *Pediatr Pulmonol*. 2013;48(6):525–537. © 2013 Wiley Periodicals, Inc. Reprinted by permission of John Wiley & Sons, Inc.

β-Lactam antibiotics can be administered as an intermittent, prolonged, or continuous infusion. Prolonged or continuous infusions are designed to maximize the time the concentrations exceed the minimum inhibitory concentration.[101] This is particularly important in patients with CF because of the rapid clearance (excellent renal function) and reduced susceptibility of the organisms within the airways.[102]

Extended-interval dosing of aminoglycosides (every 24 hours compared with every 8 hours) is easier and less costly to administer and potentially limits toxicity. A randomized clinical trial in children and adults with CF (*N* = 244) demonstrated equivalent efficacy as evidenced by a change in FEV_1 in ~10% in patients receiving tobramycin 10 mg/kg/day either as a single dose or in three divided doses. However, the once-daily regimen provided improved renal safety in children as evidenced by serum creatinine and urinary *N*-acetyl-β-D-glucosaminidase, a biomarker of renal proximal tubular injury.[103] An evidence-based review conducted by the CFF concluded that once-daily dosing of aminoglycosides is preferable to three times-daily dosing for treatment of an acute exacerbation of the pulmonary disease.[99]

Routine monitoring of serum aminoglycoside concentrations is recommended to maximize efficacy and minimize the risk of toxicity. Because many patients with CF receive multiple courses of aminoglycosides, sometimes for extended durations, they are particularly predisposed to the toxicities. With once-daily dosing, the trough concentrations are expected to be unmeasurable by design (eg, dosing interval exceeds 5 half-lives). Therefore, serum concentrations are typically obtained between 1 to 2 and 6 to 8 hours after the end of the infusion. The two levels can then be used to determine the extrapolated peak concentration (target 20–30 mg/L) and the area under the serum concentration–time curve (target 72–100 mg/L × hour).[104]

CASE 21-3

QUESTION 1: B.W., a 19-year-old male, was diagnosed with CF at age 3 years after a history of chronic pneumonias. His CFTR genotype is *F508del/R117H*. He presents to the pulmonary clinic with increasing cough and sputum production during the past 2 weeks, with a change in sputum color from white to green. He was last admitted for treatment of an acute pulmonary exacerbation 6 months ago. He currently weighs 99.64 pounds (45.2 kg) and states he has lost 4 pounds (1.81 kg). B.W. is a slightly thin adult male whose breathing is labored. Pulmonary function tests reveal an FEV_1 of 75% of predicted and an FVC of 70% (his usual baselines are FEV_1, 85%, and FVC, 80%). *P. aeruginosa*

grew out of his sputum sample taken at the clinic 4 weeks ago and demonstrated susceptibility to ceftazidime, piperacillin, imipenem, tobramycin, and colistin and intermediate susceptibility to ciprofloxacin. Other pertinent laboratory findings are as follows:

White blood cell count, 17,000/μL, with 4% bands, 35% segmented neutrophils, 50% lymphocytes, and 11% eosinophils
Blood urea nitrogen (BUN), 7 mg/dL
Creatinine, 0.5 mg/dL

All other blood work, liver function tests, and electrolytes are within normal limits. Heart rate and blood pressure are normal. Temperature is 99.2 °F (37.33 °C), respiratory rate is 25 breaths/minute with an oxygen saturation of 95%. A number of new pulmonary infiltrates are seen on chest radiograph. His current medications include the following: one fat-soluble vitamin twice daily, two microencapsulated pancreatic enzyme capsules (16,000 units of lipase/capsule) with meals, and one or two capsules with snacks as needed, dornase alfa 2.5 mg nebulized daily, and elexacaftor 100 mg, tezacaftor 50 mg, ivacaftor 75 mg two tablets in the morning and ivacaftor 150 mg in the evening.

What subjective and objective findings does B.W. exhibit that would lead to the diagnosis of a pulmonary exacerbation?

B.W. demonstrates an increase in sputum production (purulent), increased cough, dyspnea, weight loss, and a 10% decline in pulmonary function tests from baseline. B.W. also has a mild fever and elevated white blood cell count; however, an increase in white blood cell count, fever, or appearance of a new infiltrate on chest radiograph may or may not be present in all cases of pulmonary exacerbations.

Case 21-3, Question 2: B.W. is admitted to the hospital for treatment of an acute pulmonary exacerbation. What would be an appropriate antimicrobial treatment plan for B.W. based on his current laboratory data?

Based on these findings and the in vitro susceptibility results, it would be reasonable to initiate a regimen of ceftazidime or piperacillin–tazobactam in combination with tobramycin. Ciprofloxacin is not optimal in this instance because of reduced susceptibility. Imipenem and colistin are typically reserved for the treatment of resistant *P. aeruginosa* infections.

Ceftazidime 2 g IV every 6 hours could be administered to B.W. by intermittent, 3-hour prolonged infusion, or a 2-g loading dose administered for 30 minutes followed by 6 g as a continuous infusion. Data from a large randomized trial demonstrated similar efficacy and safety between intermittent and continuous infusion ceftazidime in patients with CF; however, the continuous infusion treatment was associated with greater improvement in pulmonary function in those infected with resistant strains. In addition, continuous infusion resulted in a significantly prolonged interval between exacerbations.[102]

In B.W., the preferred initial dosing regimen of IV tobramycin would be 440 mg (10 mg/kg) every 24 hours. Target peak concentrations of 20 to 30 mg/L should be verified after the first or second dose. Target area under the concentration–time curve should be 72 to 100 mg/L × hour. Tobramycin concentrations should be measured at least every 7 days while B.W. is on therapy. In addition, serum concentrations of BUN and creatinine should be measured three times weekly for early detection of acute kidney injury.

The antibiotics should be administered for 2 weeks. After the initiation of antibiotics in this hospitalization, home IV antibiotic therapy should be a consideration for B.W.[105] The decision as to whether a patient is a good candidate for home IV antibiotic therapy is based on initial response as well as the expected level of support provided to the patient at home. In particular, the ability of the patient to maintain nutritional and intensive airway clearance programs established in the hospital needs to be assessed. The duration of B.W.'s antibiotic therapy should be based on his clinical response. Ideally, his pulmonary function (eg, FEV_1) should improve by 10% to 20% and should be evaluated weekly. The purulent nature and volume of the sputum should decrease, and a gradual overall improvement in subjective feeling should be noted. Improved appetite and increased weight gain should be assessed daily to reach baseline weight (increase of 1–2 kg/week). For patients receiving repeated courses of IV aminoglycosides, periodic audiometric testing is recommended.

CHRONIC MAINTENANCE THERAPY WITH ORAL OR INHALED ANTIBIOTICS

Recognition of the progressive decline in pulmonary function despite aggressive treatment of acute exacerbations and the availability of oral and inhaled therapies with activity against typical CF pathogens have led to increased use of chronic maintenance antibiotic therapy. The goal of chronic maintenance therapy is to suppress bacterial infection to reduce the frequency and severity of pulmonary exacerbations and to slow the progressive deterioration in lung function. Inhaled antibiotics include tobramycin, aztreonam, and colistimethate. Inhaled antibiotics are desirable because of the relatively high sputum concentrations and low systemic bioavailability, which maximizes efficacy and minimizes toxicity.

Tobramycin for inhalation

Results of phase 3 studies of inhaled tobramycin conducted during a 6-month interval demonstrated significant improvement in pulmonary function (relative difference in FEV_1 of 10%), a reduction in the risk of hospitalization (37%), and a reduced need for IV antipseudomonal antibiotics (32%).[106] A significantly greater proportion of patients in the treatment arm reported hoarseness; however, this did not require discontinuation and improved with time. In addition, some patients report a bitter taste to this preparation; however, this typically does not result in discontinuation of the medication. The recommended dosage of tobramycin nebulizer solution is 300 mg twice daily in a cycle of 28 days on and 28 days off. Tobramycin for inhalation is provided as a premixed solution contained in unit dose vials and requires refrigeration before use. Tobramycin for inhalation is administered via a vented jet nebulizer system (Pari LC Plus) to ensure consistent particle size and outflow characteristics. Based on the results of the phase 3 studies, inhaled tobramycin is indicated in patients age older than 6 years with repeated sputum cultures demonstrating *P. aeruginosa* and FEV_1 between 25% and 75% of predicted.[67] A dry powder formulation of tobramycin for inhalation (TOBI® podhaler®) also exists, which offers the advantages of

shortened administration time, no need for refrigeration, and easy portability. TOBI® podhaler® is provided in 28-mg capsules and is administered as four capsules twice daily in a cycle of 28 days on and 28 days off. Several retrospective analyses have demonstrated a potential drug interaction between tobramycin and azithromycin. In particular, a retrospective cohort study using the CFF registry data found that patients receiving inhaled aztreonam and azithromycin experienced a slower rate of lung function decline when compared with matched controls receiving inhaled tobramycin and azithromycin.[107] Potential issues with selection bias preclude the determination of a direct cause and effect relationship. A prospective controlled trial (https://clinicaltrials.gov/ct2/show/NCT02677701) is currently being conducted and is expected to provide definitive evidence of the significance of this potential drug interaction.

Aztreonam lysine solution for inhalation

Two phase 3 trials evaluated the short-term safety and efficacy of aztreonam lysine solution for inhalation.[106,108] The results of these trials demonstrated a significant improvement in respiratory symptoms assessed using a patient-reported outcome instrument, and a significant delay in the need for inhaled or IV antipseudomonal antibiotics is determined by the presence of pulmonary exacerbation symptoms. The most common adverse effects are cough and wheezing. Bronchodilator use is recommended before each dose to reduce these symptoms. The recommended dosage of aztreonam lysine is 75 mg three times daily for 28 days. Aztreonam is provided in a powder form that requires reconstitution with saline before administration. Aztreonam requires refrigeration before use. A special nebulizer device is required for administration (Altera), which delivers the drug in a relatively short time (eg, 2–3 minutes). Based on the results of these studies, aztreonam lysine is indicated in patients age 6 years or older with *P. aeruginosa* to improve respiratory symptoms. Aztreonam is particularly useful in patients who are intolerant of inhaled tobramycin or as add-on therapy in

those with frequent exacerbations or continued decline in pulmonary function.

Colistimethate

Colistimethate is a prodrug of colistin, an antibiotic in the polymyxin family. Colistimethate is available only in an IV powder formulation in the United States and requires reconstitution before nebulization. Clinical trials evaluating the safety and efficacy of colistimethate in CF are limited by the small number of patients enrolled in the trials. Based on the lack of data, colistimethate is not recommended for routine use.[67] Colistimethate may be useful in patients infected with MDR *P. aeruginosa* or those intolerant to other inhaled antibiotics. Adverse effects associated with inhaled colistimethate include cough and bronchospasm. Bronchodilators should be used before each dose. In addition, colistimethate tends to foam on nebulization, resulting in incomplete drug administration. The typical dose of colistimethate is 75 mg twice daily.

The cost of inhaled antibiotics is relatively high (tobramycin solution for inhalation $3800/month, https://www.drugs.com/price-guide/tobi); aztreonam lysine solution for inhalation $4900/month, https://www.drugs.com/price-guide/cayston; however, use of inhaled antibiotics reduces hospital days, leading to substantial savings in direct medical costs that may offset its acquisition price. The cost-effectiveness of inhaled antibiotics would be expected to be greatest in patients experiencing relatively frequent exacerbations (two or more hospital admissions per year). A short-term trial (eg, 1–2 months) is warranted in patients with CF chronically colonized with *P. aeruginosa* to assess improvement in pulmonary function. A longer trial period (eg, up to 1 year) may be necessary to assess the impact on hospitalizations. Patients should be instructed in the proper use and maintenance of the nebulizer and compressor system used in its delivery. In particular, it is important to wash reusable nebulizers between uses to avoid the buildup that can reduce their effectiveness. The nebulizers can be hand washed with liquid dish soap or placed in the top rack of a dishwasher for cleaning. After

each cleaning, the nebulizer should be allowed to dry before reusing to reduce bacterial contamination. Regular sterilization is required to reduce the potential for bacterial contamination. In addition, the patient should be instructed not to dilute or mix antibiotic solutions with other drugs in the nebulizer, which can alter the delivery characteristics. Inhaled antibiotics are typically administered after the bronchodilator, dornase alfa, and airway clearance therapies to maximize retention time within the airways.

Azithromycin

Oral azithromycin is frequently prescribed to patients with CF owing to its anti-inflammatory and antivirulence properties. The macrolide antibiotics do not exhibit significant antibacterial activity against *P. aeruginosa* using conventional susceptibility testing methods; however, they do inhibit alginate production, the principal component of biofilms. Because of its favorable pharmacokinetics and reduced potential for drug interactions, most studies have evaluated azithromycin. Results of a multicenter randomized controlled trial demonstrated treatment with azithromycin was associated with a significant improvement in FEV_1 (6%) and a reduction in hospitalizations for acute pulmonary exacerbations (44%).[109] The beneficial effect of azithromycin on pulmonary function was additive with other chronic therapies such as aerosolized tobramycin and dornase alfa. Azithromycin is generally well tolerated. Nausea, vomiting, and wheezing are the most common adverse effects reported. Based on current data, azithromycin is indicated in patients older than 6 years who are colonized with *P. aeruginosa.*[95] Based on the pivotal trial, the dose of azithromycin is 500 mg three times/week for patients weighing >88.18 pounds (40 kg) and 250 mg three times weekly for patients weighing <88.18 pounds (40 kg). One contraindication to treatment with azithromycin is colonization with mycobacteria because of the potential for the development of resistance.

Case 21-3, Question 3: B.W. comes to the outpatient clinic 2 weeks after hospital discharge for a follow-up visit and reports a significant reduction in cough and sputum production, and no shortness of breath. Spirometry reveals an FEV_1 of 85% of predicted. He has resumed his outpatient treatment regimen, which includes one multiple vitamin every day, two microencapsulated pancreatic enzyme capsules (16,000 units of lipase/capsule) with meals, and one or two capsules with snacks as needed, dornase alfa 2.5 mg nebulized daily, and elexacaftor 100 mg, tezacaftor 50 mg, ivacaftor 75 mg two tablets in the morning, and ivacaftor 150 mg in the evening. What changes, if any, should be made to B.W.'s treatment regimen?

Because B.W. has had two exacerbations in the last 6 months, he would benefit from the addition of medications to reduce the frequency of exacerbations. In addition to the disruption to his life, frequent exacerbations are associated with a more rapid decline in pulmonary function and reduced survival.[110] Key pharmacologic therapies demonstrated to improve pulmonary function and reduce the frequency of pulmonary exacerbations include dornase alfa, inhaled tobramycin or aztreonam, IHS, and azithromycin. B.W. is already receiving dornase alfa but is not on inhaled tobramycin or aztreonam, IHS, or azithromycin. One important consideration when adding new therapies is the treatment burden, particularly with inhaled therapies. Inhaled tobramycin 112 mg twice daily via the podhaler cycled for 28 days on and 28 days off and oral azithromycin 500 mg every Monday, Wednesday, and Friday would be appropriate additions to the treatment regimen because B.W. is chronically infected with *P. aeruginosa,* and these particular agents demonstrated the greatest improvement in pulmonary function when compared with IHS. In addition, azithromycin has a minimal effect on treatment burden as it can be administered orally 3 days a week. IHS would also be of benefit by reducing exacerbation frequency; however, it could be added in the future if B.W. demonstrates a decline in pulmonary function or increased frequency of exacerbations despite the new additions.

Oral antibiotics

Case 21-3, Question 4: One year later, B.W. returns to the clinic exhibiting signs and symptoms of a mild exacerbation but refuses IV antibiotics or hospitalization, because he is in the middle of final examinations. What alternative to IV therapy is available to treat B.W.?

The quinolone family of antibiotics is currently the only option for oral treatment of *P. aeruginosa.* Emergence of resistant strains of *Staphylococcus* and *Pseudomonas* species has led the CF medical community to restrict the use of quinolones in the treatment of acute CF exacerbations.[111,112] Oral fluoroquinolones (eg, ciprofloxacin) have become widely used in patients with CF because they are less expensive, easy to administer, and as effective as IV therapy in an acute exacerbation.[113,114]

Because of the past sensitivities of B.W.'s organisms and his refusal to be admitted to the hospital, ciprofloxacin 1000 mg orally twice daily for 1 week can be initiated in addition to the aerosolized tobramycin and oral azithromycin.[115] After 1 week of the combined aerosol and oral therapies, B.W. should be reevaluated for hospital admission if his condition worsens, or his therapy can be continued if his condition improves.

Case 21-3, Question 5: B.W. returns to the outpatient clinic 3 months later for his annual comprehensive visit. Results of laboratory studies, dual-emission X-ray absorptiometry (DXA) scan, spirometry, and an OGTT are as follows:

BUN, 10 mg/dL
Creatinine, 0.6 mg/dL
Urine microalbumin/creatinine, 12 µg/mg
2-hour OGTT plasma glucose, 220 mg/dL
Glycosylated hemoglobin, 7.8%
DXA Z-score, –2.1 (pelvis)
FEV_1, 83% of predicted

How should these laboratory studies be interpreted and what new therapies would you recommend?

The elevated 2-hour OGTT plasma glucose indicates B.W. has CF-related diabetes mellitus. This is confirmed by the elevated

glycosylated hemoglobin. The urine microalbumin testing indicates that B.W. is not spilling protein into the urine as a result of the CF-related diabetes mellitus. Treatment with insulin should be initiated in B.W. to improve nutritional status and prevent microvascular complications. The DXA scan results indicate B.W. has osteopenia and should be initiated on calcium 500 mg orally twice daily, and his vitamin D status should be determined. Treatment of osteopenia is recommended to prevent progression to osteoporosis, which would put the patient at risk for fractures. In addition, osteoporosis is a relative contraindication for lung transplantation because of the risk for fractures after transplantation that may impair adequate recovery.

B.W.'s spirometry results indicate that his pulmonary function is stable, and his current pharmacotherapeutic regimen should be continued.

CASE 21-3, QUESTION 6: During his clinic visit, B.W. is noted to have oral thrush and is prescribed fluconazole 200 mg on the first day and 100 mg daily for a 14-day treatment course. Are any adjustments needed to B.W.'s treatment regimen with the addition of fluconazole?

Fluconazole is a moderate CYP3A inhibitor and therefore would be expected to reduce the metabolism of elexacaftor, tezacaftor, and especially ivacaftor. The dose should be reduced to two elexacaftor/tezacaftor/ivacaftor tablets and one ivacaftor tablet on alternate days when coadministered with fluconazole. The evening dose of ivacaftor should not be taken.

LUNG TRANSPLANTATION

Pulmonary disease progression leading to eventual respiratory failure is an inevitable consequence of the chronic cycle of airway obstruction, infection, and inflammation. End-stage lung disease (defined by an FEV_1 of <30% of predicted) significantly affects the quality of life for patients with CF as a result of reduced exercise

tolerance, heavy treatment burden, need for oxygen therapy, and frequent hospitalizations for pulmonary exacerbations. Lung transplantation is a potential therapeutic option for CF patients with end-stage lung disease.[116] The optimal time to refer a patient for lung transplantation is not precisely defined; however, patients are typically referred when their FEV_1 is ~40% to maximize the chances of obtaining new lungs before the patient experiences respiratory failure. Transplant evaluation includes assessments of pulmonary disease severity, patient adherence to therapies, and concomitant illnesses. Once accepted into the program, the patient is placed on the transplant list awaiting the availability of potential organs. The waiting time to receive a lung transplant is highly variable and depends on the Lung Allocation Score, a score that distributes organs based on model-predicted benefit from transplantation. The mean survival after lung transplantation is ~50% at 5 years. Importantly, the quality of life for many lung transplant recipients improves significantly.

Nausea and Vomiting

Lisa M. DiGrazia and J. Todd Carter

CORE PRINCIPLES		CHAPTER CASES
MOTION SICKNESS		
1	Motion sickness is caused by discordant information about body position or motion received from visual, vestibular, or body proprioceptors. Acetylcholine is thought to be the primary neurotransmitter involved.	**Case 22-1 (Question 1)**
2	Transdermal scopolamine is recommended for prophylaxis of motion sickness for moderate-to-severe stimuli. Dimenhydrinate or promethazine is recommended for treatment of breakthrough symptoms. The most common adverse effects of these agents include drowsiness, confusion, and dry mouth.	**Case 22-1 (Questions 2, 3), Table 22-1**

CORE PRINCIPLES		CHAPTER CASES
CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING		
1	Nausea and vomiting are initiated by several stimuli and mediated by several neurotransmitters in the central nervous system, peripheral nervous system, and gastrointestinal tract. Because of the multiple neurotransmitter receptors involved, successful prophylaxis and treatment of chemotherapy-induced nausea and vomiting will almost always require medications with more than one mechanism of action.	**Case 22-2 (Question 1)**
2	The likelihood of nausea and vomiting depends on patient risk factors and, most importantly, on the emetogenicity of the chemotherapy agents prescribed. The antiemetic regimen should be appropriate for the chemotherapy agent with the highest emetogenicity level.	**Case 22-2 (Question 1), Table 22-2**
3	Patients receiving moderate to highly emetogenic chemotherapy should receive prophylaxis with an aprepitant-, netupitant-, or olanzapine-containing regimen. The backbone of these regimens includes a 5-hydroxytryptamine receptor type 3 (5-HT_3) antagonist and dexamethasone.	**Case 22-2 (Question 2), Tables 22-3, 22-4, Figures 22-2, 22-3**

CORE PRINCIPLES		CHAPTER CASES
4	For breakthrough symptoms, patients should receive rescue antiemetics with a mechanism of action different from the prophylactic medications and receive more aggressive antiemetics before the next cycle of chemotherapy.	**Case 22-2 (Question 3), Tables 22-3, 22-4, Figures 22-2, 22-3**
RADIATION-INDUCED NAUSEA AND VOMITING		
1	Radiation can cause nausea and vomiting by the same pathways as chemotherapy. The risk depends on the area and size of the radiation field as well as the fractional dose of radiation and whether the patient has had chemotherapy in the past.	**Case 22-3 (Question 1), Table 22-5**
2	The recommended prophylaxis for radiation-induced nausea and vomiting includes a 5-HT_3 antagonist with dexamethasone for high-risk patients and with or without dexamethasone for patients at moderate risk. Breakthrough symptoms may be treated with a 5-HT_3 antagonist or dopamine antagonist.	**Case 22-3 (Question 1), Table 22-5**
POSTOPERATIVE NAUSEA AND VOMITING		
1	The risk of postoperative nausea and vomiting depends on several patient-related, surgical, and anesthetic factors. The antiemetic regimen should be proportional to the risk factors.	**Case 22-4 (Question 1), Table 22-6**

CORE PRINCIPLES		CHAPTER CASES
2	The most active agents in preventing postoperative nausea and vomiting are 5-HT_3 antagonists. For patients at moderate to high risk, a 5-HT_3 antagonist should be combined with dexamethasone or droperidol. Antiemetics used for rescue therapy should be of a class different from the prophylactic agents used.	**Case 22-4 (Question 1), Table 22-6**

INTRODUCTION

Nausea and vomiting are unpleasant symptoms caused by self-limiting disorders or serious conditions such as cancer. These symptoms can range from mild, short-lived nausea to continuing severe emesis and retching. The emetic response can be described in three phases: nausea, vomiting, and retching. *Nausea* is the subjective feeling of the need to vomit. It includes an unpleasant sensation in the mouth and stomach and can be associated with salivation, sweating, dizziness, and tachycardia. *Vomiting* is the forceful expulsion of the stomach contents through the mouth but is preceded by the relaxation of the esophageal sphincter, contraction of the abdominal muscles, and temporary suspension of breathing. *Retching* is the rhythmic contraction of the abdominal muscles without actual emesis. It can accompany nausea or occur before or after emesis.

EPIDEMIOLOGY AND CLINICAL PRESENTATION

Nausea and vomiting are caused by many disorders. Central nervous system (CNS) causes include increased intracranial pressure, migraine headaches, brain metastases, vestibular dysfunction, alcohol intoxication, and anxiety. Infectious disease causes include viral gastroenteritis, food poisoning, peritonitis, meningitis, and urinary tract infections. Metabolic causes include hypercalcemia, uremia, hyperglycemia, and hyponatremia. Gastrointestinal (GI) disorders, such as gastroparesis, bowel obstruction, distension, and mechanical irritation, can cause nausea and vomiting. Among the many medications that can cause nausea and vomiting are cancer chemotherapy, antibiotics, antifungals, and opiate analgesics.

In addition to the suffering involved, uncontrolled vomiting can lead to dehydration, electrolyte imbalances, malnutrition, aspiration pneumonia, and esophageal tears. Nausea and vomiting often reduce food intake and can impair a person's ability to care for himself or herself. Significant reductions in quality-of-life scores have been demonstrated in patients with cancer having chemotherapy-induced nausea and vomiting (CINV) compared with patients who did not have those symptoms.[1]

PATHOPHYSIOLOGY

The CNS, the peripheral nervous system, and the GI tract are all involved in initiating and coordinating the emetic response. In the CNS, the vomiting center (VC) receives incoming signals from other parts of the brain and the GI tract and then coordinates the emetic response by sending signals to the effector organs. The VC is located in the medulla oblongata of the brain, near the nucleus tractus solitarius (NTS). The VC is stimulated by neurotransmitters released from the chemoreceptor trigger zone (CTZ), the GI tract, the cerebral cortex, the limbic system, and the vestibular system (**Fig. 22-1**). The major neurotransmitter receptors associated with the emetic response include serotonin (the 5-hydroxytryptamine type

3 [5-HT_3]) receptors, neurokinin 1 (NK1) receptors, and dopamine receptors. Other receptors involved include corticosteroid, acetylcholine, histamine, cannabinoid, gabaminergic, and opiate receptors. Many of these receptors are targets for antiemetic therapy.

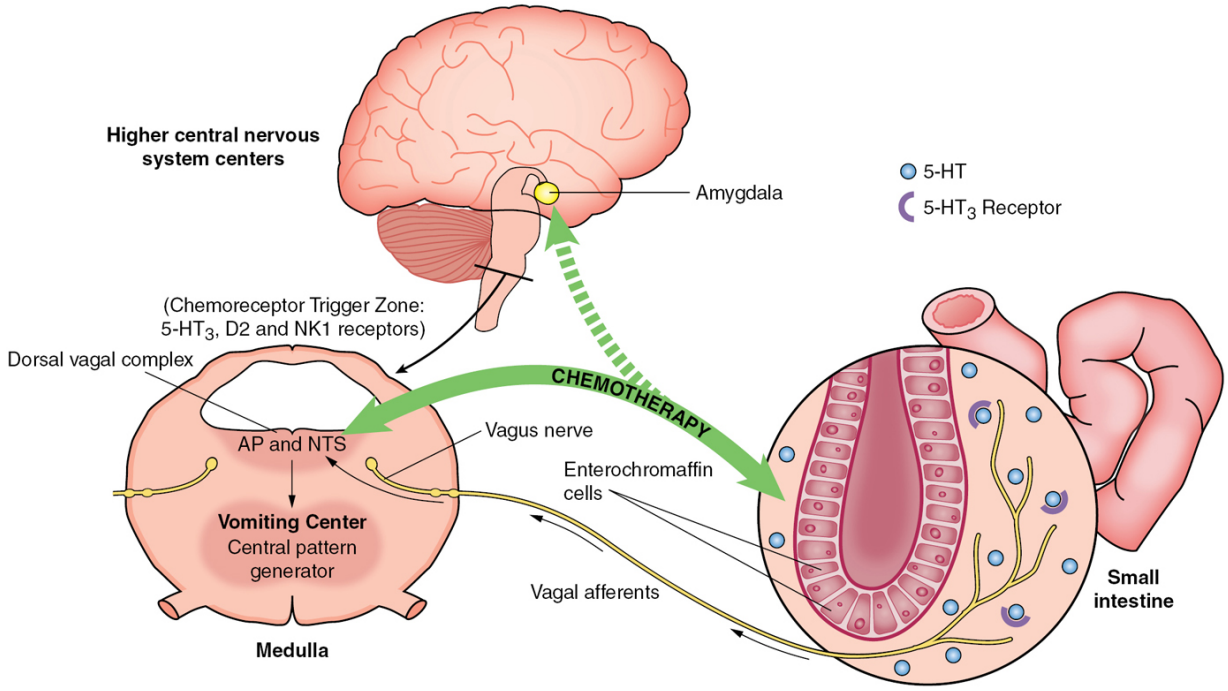

Figure 22-1 Pathways by which chemotherapeutic agents may produce an emetic response. 5-HT, 5-hydroxytryptamine; 5-HT_3, 5-hydroxytryptamine type 3 receptor; AP, anterior pituitary; D, days; NTS, nucleus tractus solitarius.

In the CNS, the CTZ is located in the area postrema on the floor of the fourth ventricle in the brainstem; it lies outside the blood–brain barrier. When the CTZ senses toxins and noxious substances in the blood or cerebrospinal fluid, it triggers the emetic response by releasing neurotransmitters that travel to the VC and NTS. The major neurotransmitter receptors include serotonin, dopamine, and NK1.

The GI system also plays a large part in the initiation of the emetic response. The GI tract contains enterochromaffin cells in the GI mucosa. When these cells are damaged by chemotherapy, radiation, anesthetics, or mechanical irritation, serotonin is released, which can

stimulate the vagal afferents as well as directly stimulate the VC and NTS. The VC then initiates the emetic response.

The cerebral cortex and limbic system can stimulate the emetic center in response to emotional states, such as anxiety, pain, and conditioned responses (anticipatory nausea and vomiting). The neurotransmitters involved in this pathway are less well understood. Disorders of the vestibular system, such as vertigo and motion sickness, stimulate the VC through acetylcholine and histamine release.

DIAGNOSIS

The initial evaluation of the patient with nausea and vomiting should include the onset of symptoms, the severity and duration of symptoms, hydration status, precipitating factors, current medical conditions and medications, and food and infectious contacts. The etiology of nausea and vomiting should be determined, if possible, so that underlying conditions can be treated specifically. Supportive treatment should be initiated, if needed, including fluid and electrolyte replacement. If the nausea and vomiting is mild and self-limited, antiemetic therapy may not be required. For others, however, the appropriate antiemetic therapy will depend on the patient and the etiology of the nausea and vomiting.

MOTION SICKNESS

Clinical Presentation and Risk Factors

CASE 22-1

QUESTION 1: P.C. is a 27-year-old female who has no significant medical history, with the exception of moderate dysmenorrhea and motion sickness

associated with travel by air. Previously, she has taken dimenhydrinate before airplane trips with moderate success. She is engaged to be married, and she and her fiancé have decided on a weeklong Caribbean cruise for their honeymoon. P.C. is concerned that she may also develop seasickness and that dimenhydrinate may not control her symptoms, particularly in the event of rough weather at sea.

Will P.C. be at higher risk for motion sickness?

The symptoms of motion sickness occur in response to an unusual perception of real or apparent motion. In these situations, there is sensory conflict about body position or motion through the visual, vestibular, or body proprioceptors. Acetylcholine is thought to be the primary neurotransmitter involved in signaling the VC, as is histamine, but to a lesser extent. Adrenergic stimulation can block this transmission. Although nausea may be the first symptom recognized by the patient, other mild symptoms often proceed including an awareness of the stomach (ie, a sensation of fullness), hypersalivation, facial pallor, belching, yawning, and heartburn.[2] The milder symptoms may then progress to diaphoresis, flushing, hyperventilation, increased body warmth, and, ultimately, emesis. The risk of motion sickness varies between ages and genders. The risk is lowest in children younger than 2 years old and highest in children 2 to 12 years old and is more likely to occur in biologic females than in biologic males.[3] In some individuals, sensitivity to motion sickness diminishes with time.[4] Boat travel is most likely to cause symptoms with air, car, and train travel occurring less frequently.[5,6] Severity of the motion sickness is highly dependent on the individual and the circumstances at the time (eg, consumption of food or alcohol). Other contributing factors include weather and the patient's position in the plane, vehicle, or boat. Because of P.C.'s history and her travel plans, she is at high risk for recurrence of her motion sickness symptoms.

Nonpharmacologic Measures

Case 22-1, Question 2: What nonpharmacologic methods could P.C. employ to reduce her chance of developing motion sickness?

Nonpharmacologic measures or natural remedies may be useful for reducing motion sickness.[4] These include riding in the middle of the boat or plane where the motion is less dramatic, lying in a semirecumbent position, driving the vehicle or sitting in the front passenger seat, choosing a window seat, maintaining hydration while avoiding carbonated beverages or alcohol, fixing the vision on the horizon, avoiding reading, and closing the eyes if below deck, in the backseat, or in the cabin.[3] Many people recommend keeping active on a ship to "get their sea-legs" faster through habituation. The effectiveness of acupressure at the P6 point of the wrist (about three fingerbreadths above the wrist) is unclear. A controlled-stimulus trial compared two brands of wristbands with placebo; neither band was more effective than was placebo in preventing symptoms of motion sickness.[7] Studies of ginger preparations also are equivocal. The action of ginger may be through enhanced gastric emptying and not on the vestibular system.[8,9]

Overview of Treatment

Case 22-1, Question 3: For P.C., what medications are available to prevent and treat motion sickness symptoms?

Anticholinergic agents and antihistamines that cross the blood–brain barrier effectively prevent and treat motion sickness.[5,6] Antihistamines frequently used include dimenhydrinate, meclizine, cyclizine, and promethazine.[10] In general, these medications are more effective in preventing than in treating established symptoms. Sympathomimetics and amphetamines have shown effectiveness in the treatment of motion sickness, but owing to addictive potential and or controlled status, they are not used as often.[11] Benzodiazepines have been used but are not as effective as other

treatments. Diazepam has been shown to prevent motion sickness, but the sedative effects may limit its use.[11] The 5-HT_3 receptor antagonists and NK1 receptor antagonists have not been shown to be effective in preventing motion sickness.[4,8] Nonsedating antihistamines are not as effective as other antihistamines because they do not sufficiently cross the blood–brain barrier.[4,5] Scopolamine has been well studied for the prevention of motion sickness and is highly effective.[4,12] In a controlled trial, scopolamine was more effective than was promethazine, and both were more effective than placebo, meclizine, or lorazepam.[13] Scopolamine is available as a topical patch, which bypasses the problem of GI symptoms associated with motion sickness. **Table 22-1** summarizes medications effective for the prevention and treatment of motion sickness.

Table 22-1
Medications for Prevention or Treatment of Motion Sickness in Adults

Medication (Trade Name)	Dosage	Recommended Use	Adverse Effects
Scopolamine (Transderm-Scop®)	1 mg TOP behind the ear every 3 days Apply at least 4 hours before exposure.	Prevention of nausea/vomiting associated with motion sickness and recovery from anesthesia and surgery	Xerostomia, dizziness, agitation, drowsiness, blurred vision, confusion, fatigue
Dimenhydrinate (Dramamine®)	50–100 mg PO every 4–6 hours (max 400 mg/day). May be taken PRN or on a scheduled basis if required.	Prevention and treatment of nausea, vomiting, or dizziness associated with motion sickness	Drowsiness or excitement, dry mouth, thickening of secretions, dizziness, blurred vision, tachycardia, fatigue
Promethazine (Phenergan®)	12.5–25 mg PO every 4–6 hours. May be taken PRN or on a scheduled basis if required. (Some experts recommend a maximum dose of 50 mg/day to avoid intolerable side effects.)	Although included as an FDA-approved use in the manufacturer's prescribing information, other therapies are available without the risks associated with promethazine use.[2]	Drowsiness, bradycardia, xerostomia, confusion, dizziness
Meclizine (Dramamine® Less Drowsy [OTC], Bonine® [OTC], Motion-Time® [OTC], Travel Sickness® [OTC], Travel-Ease® [OTC])	25–50 mg PO 1 hour before travel. Repeat every 24 hours if needed.	Prevention and treatment of nausea, vomiting, or dizziness associated with motion sickness	Drowsiness, dizziness, fatigue, xerostomia, headache, blurred vision

OTC, over the counter; PO, oral; PRN, as needed; TOP, topical patch.

Source: Data from Facts & Comparisons. Accessed September 23, 2022. https://fco.factsandcomparisons.com/lco/action/home.

Because P.C. is susceptible in a moderate-to-severe stimulus situation, prevention with a scopolamine patch applied behind the

ear every 3 days, starting at least 4 hours before departure, should be recommended. If she experiences breakthrough symptoms, dimenhydrinate or promethazine may be useful. She should be advised about the potential adverse effects of these agents, which include drowsiness, confusion, and dry mouth.

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

CINV occurs in many patients receiving chemotherapy for cancer.[1] The mechanisms of the emetic response described at the beginning of this chapter apply to CINV as well. The major neurotransmitter receptors involved in these pathways include 5-HT_3, NK1, and dopamine receptors. CINV can occur in different phases. Acute-onset CINV symptoms occur within a few minutes to hours of the administration of chemotherapy. These symptoms often peak several hours after administration and can last for the first 24 hours. Some antineoplastic agents can also cause nausea and vomiting symptoms for a longer time after chemotherapy administration. These delayed-onset CINV symptoms peak in about 2 to 3 days and can last 6 to 7 days. Some patients may experience acute symptoms without delayed symptoms or delayed symptoms without acute symptoms, whereas others experience CINV in both. Some patients who have received previous chemotherapy treatments may experience a conditioned response in which they have symptoms even before chemotherapy begins. This is called *anticipatory nausea and vomiting* and is difficult to treat because it is primarily triggered by poor nausea and vomiting control in previous cycles. Breakthrough nausea and vomiting occur if the primary prophylactic antiemetics fail to work completely. Of course, regardless of the time course and cause, these are very distressing, unpleasant, and disruptive symptoms for the patient.

The likelihood of CINV depends on several factors.[1] Patient-related factors that increase the risk of acute-onset CINV include age younger than 50 years, female sex, previous history of CINV, history of motion sickness or nausea with pregnancy, anxiety, or depression. A significant history of alcoholism actually protects against CINV. Delayed symptoms are more common in females, in those who have had poor emetic control in the acute phase, and in patients with anxiety or depression.

Chemotherapy-related factors also predict the likelihood of symptoms. Factors such as shorter infusion time, higher dose, and more chemotherapy cycles increase the risk of CINV. With multiday chemotherapy regimens, the symptoms usually peak around the third to the fourth day of chemotherapy, when the acute symptoms caused by the later days' doses overlap with the delayed symptoms from the first days' doses. The most predictive factor, however, is the chemotherapy agent's inherent ability to cause CINV, or its emetogenicity.[1,14,15] Antineoplastics that are most likely (>90% of patients) to cause symptoms are classified as highly emetogenic chemotherapy. Agents that cause nausea and vomiting in 30% to 90% of patients are classified as moderate-risk agents. Low emetogenicity agents cause symptoms in 10% to 30% of patients. Other chemotherapy agents have a minimal risk, causing CINV in <10% of patients. **Table 22-2** lists selected chemotherapy agents in the various emetogenicity classes, noting that references differ in the estimation of emetic risk for some antineoplastic agents. The emetogenicity risk also depends on the dosage used and the route of administration.

Table 22-2
Emetogenicity of Selected Intravenous and Oral Antineoplastic Agents With Prophylaxis Options

Potential	Chemotherapy		Prophylaxis Options
Intravenous high emetic risk (>90% frequency of emesis)	AC combination defined as anthracycline with cyclophosphamide Carboplatin AUC ≥4 Carmustine >250 mg/m^2 Cisplatin Cyclophosphamide >1500 mg/m^2 Dacarbazine Doxorubicin ≥60 mg/m^2 Epirubicin >90 mg/m^2 Ifosfamide ≥2 g/m^2 per dose Mechlorethamine Streptozocin		Four-drug–containing regimen (preferred) *or* Three-drug regimen (containing olanzapine) *or* Three-drug regimen (containing NK1RA)
Intravenous moderate emetic risk (30%–90% frequency of emesis)	Aldesleukin >12–15 million IU/m^2 Amifostine >300 mg/m^2 Azacitidine Bendamustine Busulfan Carboplatin AUC <4 Carmustine ≤250 mg/m^2 Clofarabine Cyclophosphamide ≤1500 mg/m^2 Cytarabine >200 mg/m^2 Dactinomycin Daunorubicin Dual-drug liposomal encapsulation of cytarabine and daunorubicin Dinutuximab Doxorubicin <60 mg/m^2	Epirubicin ≤90 mg/m^2 Enfortumab vedotin-ejfv Fam-trastuzumab deruxtecan-nxki Idarubicin Ifosfamide <2 g/m^2 per dose Interferon α ≥10 million IU/m^2 Irinotecan Irinotecan (liposomal) Melphalan Methotrexate ≥250 mg/m^2 Oxaliplatin Temozolomide Trabectedin	Three-drug regimen (containing olanzapine) *or* Three-drug regimen (containing NK1RA) *or* 5-HT$_3$RA (choose one: dolasetron, granisetron, ondansetron, or palonosetron) + dexamethasone
Intravenous low emetic risk (10%–30% frequency of emesis)	Ado-trastuzumab emtansine Aldesleukin ≤12 million IU/m^2 Amifostine ≤300 mg/m^2 Arsenic trioxide Axicabtagene ciloleucel Brentuximab vedotin Cabazitaxel Carfilzomib Copanlisib Cytarabine 100–200 mg/m^2 Docetaxel Doxorubicin (liposomal) Eribulin Etoposide 5-Fluorouracil Floxuridine Gemcitabine Gemcitabine ozogamicin Inotuzumab ozogamicin Interferon α >5 million ≤10 million IU/m^2	Ixabepilone Methotrexate >50 to 249 mg/m^2 Mitomycin Mitoxantrone Necitumumab Olaratumab Omacetaxine Paclitaxel Paclitaxel-albumin Pemetrexed Pentostatin Polatuzumab vedotin Pralatrexate Romidepsin Tagraxofusp Thiotepa Tisagenlecleucel Topotecan Ziv-aflibercept	Dexamethasone *or* Metoclopramide *or* Prochlorperazine *or* 5-HT$_3$RA (choose one: dolasetron, granisetron, ondansetron, or palonosetron)

Intravenous minimal emetic risk (<10% frequency of emesis)	Alemtuzumab Atezolizumab Asparaginase Avelumab Bevacizumab Bleomycin Bortezomib Cetuximab Cladribine Cytarabine <100 mg/m^2 Daratumumab Decitabine	Nelarabine Nivolumab Obinutuzumab Ofatumumab Panitumumab Pegaspargase Peginterferon Pembrolizumab Pertuzumab Ramucirumab Rituximab Siltuximab	No routine prophylaxis
	Denileukin diftitox Dexrazoxane Durvalumab Elotuzumab Fludarabine Interferon α ≤5 million IU/m^2 Ipilimumab Methotrexate ≤50 mg/m^2	Temsirolimus Trastuzumab Valrubicin Vinblastine Vincristine Vincristine (liposomal) Vinorelbine	
Oral moderate to high emetic risk (≥30% frequency of emesis)	Altretamine Avapritinib Binimetinib Busulfan (≥4 mg/day) Ceritinib Crizotinib Cyclophosphamide (≥100 mg/m^2/day) Dabrafenib Enasidenib Encorafenib Estramustine Etoposide	Lenvatinib (>12 mg/day) Lomustine (single day) Mitotane Niraparib Olaparib Procarbazine Rucaparib Selinexor Temozolomide (>75 mg/m^2/day)	5-HT$_3$RA
Minimal to low emetic risk (≤30% frequency of emesis)	Abemaciclib Acalabrutinib Afatinib Alectinib Alpelisib Axitinib Bexarotene Brigatinib Bosutinib Busulfan (<4 mg/day) Cabozantinib Capecitabine Chlorambucil Cobimetinib Cyclophosphamide (<100 mg/m^2/day) Dacomitinib Dasatinib Duvelisib Entrectinib Erdafitinib Erlotinib Everolimus Fludarabine Gefitinib	Loratinib Melphalan Mercaptopurine Methotrexate Nilotinib Neratinib Osimertinib Palbociclib Panobinostat Pazopanib Pomalidomide Ponatinib Regorafenib Ribociclib Ruxolitinib Sonidegib Sorafenib Sunitinib Talazoparib tosylate Temozolomide (≤ 75mg/m^2/day) Thalidomide Thioguanine Topotecan Trametinib	As needed

	Gilteritinib Glasdegib Hydroxyurea Ibrutinib Idelalisib Imatinib Ixazomib Ivosidenib Lapatinib Larotrectinib Lenalidomide	Tretinoin Trifluridine/tipiracil Vandetanib Vemurafenib Venetoclax Vismodegib Vorinostat Zanubrutinib	

5-HT_3RA, 5-hydroxytryptamine type 3 receptor antagonist; NK1RA, neurokinin 1 receptor antagonist.

Certain antineoplastic agents are more likely to cause delayed CINV symptoms. These include cisplatin, carboplatin, cyclophosphamide, doxorubicin, epirubicin, ifosfamide, and (to a lesser degree) irinotecan and methotrexate. Patients receiving more than one of these agents are at high risk for delayed symptoms.

Most chemotherapy agents are given in combination rather than as single agents. Estimating the emetogenicity of chemotherapy combinations has always been difficult. The primary literature of the regimen should always be consulted to determine the emetic risk. Should that not be available, the antiemetic regimen should be geared toward the chemotherapy agent with the highest emetogenicity level given on that day.[1,16,17] For example, in a chemotherapy combination with one high-risk agent and one with a moderate risk, the antiemetic regimen should be appropriate for the high-risk chemotherapy agent.

Antiemetic efficacy, or complete emetic response, is usually defined as no emesis and no nausea or only mild nausea in the first 24 hours after chemotherapy administration. With currently recommended antiemetic regimens, most, but not all, patients will be

protected from emesis in the acute onset (first 24 hours). Nausea is more difficult to control, whereas delayed-onset CINV symptoms are more difficult to prevent.

Overview of Treatment

Appropriate antiemetic therapy is based on the emetogenicity of the chemotherapy regimen and patient risk factors. Because the pathophysiologic response of nausea and vomiting involves many neurotransmitters, combinations of antiemetics from different therapeutic classes will be more effective in most situations than is a single agent. The predominant classes of antiemetics used for CINV include 5-HT_3 antagonists, the NK1 antagonist, and corticosteroids.

5-HYDROXYTRYPTAMINE TYPE 3 ANTAGONISTS

The 5-HT_3 antagonists inhibit the action of serotonin in the GI tract and CNS, and thereby block the transmission of emetic signals to the VC. The 5-HT_3 antagonists are both highly effective and have minimal side effects. Several agents and dosage forms in this class are now available: ondansetron, granisetron, dolasetron, and palonosetron. Dosages of these agents are shown in **Table 22-3**. The route of administration should be matched to the clinical status of the patient. Oral tablets are appropriate for most patients, but intravenous (IV), topical, or oral dissolving tablet formulations may be needed in patients who cannot take oral medications.

Table 22-3
Antiemetic Agents for Chemotherapy-Induced Nausea and Vomiting

Medication (Trade Name)	Class	Indication
Aprepitant (Emend®)	NK1RA	Acute and delayed
Dexamethasone (Decadron®)	Corticosteroid	Acute (high emetogenicity)

Medication (Trade Name)	Class	Indication
		Acute (moderate emetogenicity)
		Acute (low emetogenicity)
		Delayed
Dolasetron (Anzemet®)	5-HT_3RA	Acute Breakthrough
Dronabinol (Marinol®) capsules	Cannabinoid	Breakthrough
Dronabinol (Syndros®) oral solution	Cannabinoid	Breakthrough
Droperidol (Inapsine®)	Butyrophenone	Breakthrough
Fosaprepitant (Emend®)	NK1RA	Acute
Granisetron (Kytril®)	5-HT_3RA	Acute Breakthrough
Haloperidol (Haldol®)	Butyrophenone	Breakthrough
Metoclopramide (Reglan®)	Dopamine antagonist	Breakthrough
Lorazepam (Ativan®)	Benzodiazepine	Breakthrough
Nabilone (Cesamet®)	Cannabinoid	Refractory symptoms
Netupitant and palonosetron (Akynzeo®)	NK1RA + 5-HT_3RA	Acute (moderate or high emetogenicity)
Olanzapine (Zyprexa®)	Serotonin/dopamine antagonist	Acute (moderate or high emetogenicity)/delayed
		Breakthrough (preferred breakthrough drug of choice)
Ondansetron (Zofran®)	5-HT_3RA	Acute (moderate or high emetogenicity) Delayed
Palonosetron (Aloxi®)	5-HT_3RA	Acute/delayed
Prochlorperazine (Compazine®)	Dopamine antagonist	Breakthrough Acute

Medication (Trade Name)	Class	Indication
Promethazine (Phenergan®)	Dopamine antagonist	Breakthrough
Rolapitant (Varubi®)	NK1RA	Acute and delayed

5-HT_3RA, 5-hydroxytryptamine type 3 receptor antagonist; bid, two times daily; IM, intramuscular; IV, intravenous; NK1RA, neurokinin 1 receptor antagonist; PO, oral; PR, rectal; PRN, as needed; qid, four times daily; SL, sublingual; tid, three times daily; q6h, every 6 hours.

These agents have been widely studied, and some commonalities have emerged. All of the 5-HT_3 antagonists are considered to have equivalent efficacy.[18–23] All of these agents have a threshold effect, and so a sufficiently large dose must be given to block the relevant receptors. In addition, the dose–response curve is relatively flat, such that escalating the dose beyond the threshold dose does not enhance efficacy. When given in appropriate doses, all of these agents have similar efficacy for acute CINV, with response rates of 60% to 80%, depending on the study design.[1,16,18–23] The effectiveness of the 5-HT_3 receptor antagonists is enhanced by the addition of dexamethasone. The response rate increases by about 15% to 20% in regimens that include dexamethasone and a 5-HT_3 antagonist.[21,24] Oral and IV 5-HT_3 administration are equally effective assuming that the patient can take oral medications. The side effects of the 5-HT_3 antagonists are similar and fairly mild, and include

headache and constipation. The 5-HT_3 antagonists are one component of optimal antiemetic prophylaxis for acute CINV. However, they are not more effective than are agents from other classes (notably dexamethasone, aprepitant, or prochlorperazine) for delayed CINV.[21,25–27] The 5-HT_3 antagonists, therefore, are not generally recommended for delayed CINV. The 5-HT_3 antagonists are metabolized by different cytochrome P-450 (CYP) enzymes, including CYP1A2, CYP2D6, and CYP3A4. Differences in the metabolic rate of 5-HT_3 antagonists attributable to CYP2D6 polymorphisms might account for differences in efficacy among individual patients.[21] However, these differences are not used clinically to choose initial antiemetic therapy at this time.

Ondansetron, granisetron, and dolasetron are first-generation 5-HT_3 antagonists and have similar pharmacokinetic parameters. Palonosetron, the newest member of the 5-HT_3 antagonist family, is distinguished by a longer elimination half-life (~40 hours) than are others in its class.[28] One group of researchers described a three-drug combination of palonosetron, dexamethasone, and aprepitant in a noncomparative, phase 2 study with moderately emetogenic chemotherapy and found that the three-drug combination was safe and effective.[29]

Ondansetron, granisetron, and dolasetron have been associated with an increased risk of prolonging electrocardiographic intervals, such as QT.[30] It is not recommended to exceed maximum dosages to decrease this risk. In addition, patients should be monitored if they have an underlying cardiac disease, electrolyte abnormalities, or are concurrently taking other medications that also prolong electrocardiographic intervals.

CORTICOSTEROIDS

The mechanism of action of corticosteroids as antiemetics has not been fully determined. Some suggest that corticosteroids may decrease serotonin release, antagonize 5-HT_3, or activate corticosteroid receptors in the NTS of the medulla in the CNS.[24]

Many studies validate the effectiveness of corticosteroids in the prophylaxis of CINV symptoms. Efficacy with both dexamethasone and methylprednisolone has been described, but dexamethasone is much more widely studied and almost exclusively used. Dexamethasone improves the antiemetic control of 5-HT_3 antagonists by about 15% to 20%.[24] In addition to its use in acute-onset CINV, dexamethasone is one of the cornerstone agents used to prevent delayed-onset CINV. It is inexpensive and available in both IV and oral formulations.

The optimal dose of dexamethasone with different emetic stimuli has been studied in controlled trials.[24] For moderately emetogenic chemotherapy in the acute phase, a single 8-mg dose was as effective as larger 24 mg doses or prolonged administration. In the setting of highly emetogenic cisplatin-based chemotherapy, higher doses of 12 or 20 mg were superior to doses of 4 and 8 mg. If dexamethasone is used with aprepitant in acute onset, the lower 12-mg prechemotherapy dose is recommended because of inhibition of steroid metabolism by aprepitant (see the section on Neurokinin 1 Receptor Antagonists).[16] For prevention of delayed CINV symptoms, the most commonly used dose of dexamethasone is 8 mg twice daily on days 2 and 3 after chemotherapy without aprepitant. The dose for delayed CINV should be reduced to 8 mg daily when used with aprepitant.

Corticosteroids are sometimes underused because of the potential risk of side effects. The adverse effects of corticosteroids include insomnia, jitteriness, increased appetite, GI distress, and perineal irritation if the IV dexamethasone is infused too quickly.[22,24,31] For most patients, however, dexamethasone is well tolerated, especially because the therapy is typically short term at lower doses. Tapering the corticosteroid dose after the end of treatment for CINV is usually unnecessary because the duration of therapy is short. Patients who experience rare steroid withdrawal-like symptoms may, however, benefit from a short taper on repeated corticosteroid courses.

Corticosteroids also have antitumor properties and are a part of the antineoplastic regimen for some malignancies, such as

lymphoma, lymphoid leukemia, and myeloma, and additional dexamethasone for antiemetic protection is not necessary. In these cases, the corticosteroid should be administered just before chemotherapy to provide antiemetic activity. If aprepitant is part of an antiemetic regimen in a situation where the corticosteroid is given for antitumor reasons, the dose of the corticosteroid should not be reduced.[16]

NEUROKININ 1 RECEPTOR ANTAGONISTS

The potential use of NK1 receptor antagonists as antiemetics became apparent when the role of substance P in the peripheral nervous system and CNS was recognized in the emetic stimulus pathway. Aprepitant, the first NK1 receptor antagonist available, is active in both the acute and delayed phases of CINV caused by moderately and highly emetogenic chemotherapy. Aprepitant is usually given as a 3-day oral regimen, 125 mg on day 1 and 80 mg on days 2 and 3. Early trials determined that aprepitant could not replace a 5-HT_3 antagonist, but that it would be used best in conjunction with corticosteroids and a 5-HT_3 antagonist.[32]

Aprepitant has been studied in the prevention of CINV with highly and moderately emetogenic chemotherapy.[21,32] These studies showed improved response rates when aprepitant was added to antiemetic regimens containing a 5-HT_3 antagonist plus dexamethasone.

Although CINV symptoms tend to worsen from cycle to cycle, the effects of aprepitant seem to be maintained during four cycles of chemotherapy in patients receiving moderately emetogenic chemotherapy.[33] The addition of aprepitant to the antiemetic regimen during cycle two (even when omitted from cycle one) also seems to improve control of CINV symptoms.[34,35] For patients who have had an inadequate response to an antiemetic regimen that did not include aprepitant, it may be useful to add it in later cycles.

There is growing evidence that the prechemotherapy dose of aprepitant (or fosaprepitant) provides the majority of benefit compared with postchemotherapy doses.[21,36] The first dose of

aprepitant blocks about 80% of the NK1 receptors in the CNS.[21,36] One study compared a single 150-mg IV dose of fosaprepitant with the standard 3-day oral regimen (along with ondansetron and dexamethasone) in patients receiving highly emetogenic chemotherapy. No difference was found in the antiemetic efficacy between the two groups.[37]

Aprepitant is generally well tolerated and has mild side effects, including fatigue, hiccups, headache, and diarrhea.[32,38] The overall adverse effects in standard aprepitant-containing regimens are not appreciably different from regimens without aprepitant. Several NK1 antagonists are now available: fosaprepitant, an IV prodrug of aprepitant; an oral fixed combination capsule of an NK1-antagonist, netupitant plus palonosetron; and oral rolapitant. Netupitant and palonosetron combination therapy is recommended as an option for patients receiving highly or moderately emetogenic regimens. Trials comparing its efficacy against aprepitant have not yet been done. Rolapitant, the newest NK1 antagonist, is an oral drug with an extended half-life and should not be administered at <2-week intervals.

Aprepitant is metabolized by the CYP3A4 enzyme system. It is a moderate inhibitor and inducer of CYP3A4 and an inducer of CYP2C9.[1,32] Consequently, several drugs potentially interact with aprepitant. The most commonly encountered interaction occurs with corticosteroids. Aprepitant increases the area under the curve (AUC) of dexamethasone such that the dexamethasone dose (when used as an antiemetic) should be reduced by about one-half of the usual dose when these drugs are used together.[1,21,32] The interaction is greatest when the corticosteroid is administered orally (PO). However, when the corticosteroid is also given as part of the antitumor regimen, the corticosteroid dose should not be reduced because of concern that the antineoplastic activity might be compromised.[16] Aprepitant, fosaprepitant, and netupitant inhibit the metabolism of dexamethasone. Rolapitant does not share this interaction with dexamethasone. Aprepitant may also enhance warfarin metabolism by inducing CYP2C9. International normalized ratio (INR) values in patients treated with warfarin and the standard

aprepitant regimen are significantly reduced, especially on day 8 of the chemotherapy cycle.[21,32,39,40] The patient's coagulation status after aprepitant administration should be monitored, especially during the 7- to 10-day period after aprepitant. The dosage of warfarin should be adjusted if the INR is out of range. Several chemotherapy agents (paclitaxel, etoposide, ifosfamide, irinotecan, imatinib, vinca alkaloids, and others) are metabolized by the CYP3A4 enzyme system, and the metabolism of these agents may be altered by aprepitant. Aprepitant was used in clinical trials with some of these agents. Caution is warranted because the clinical relevance of this potential interaction is not known.[32,41] On comparing NK1-antagonists, there are fewer drug interactions with rolapitant when compared with aprepitant, fosaprepitant, and netupitant.

OLANZAPINE

Olanzapine is an atypical antipsychotic agent that antagonizes several serotonin and dopamine receptors as well as other neurotransmitter receptors.[42] Its antiemetic action was first described in patients with refractory nausea or vomiting and advanced cancer. Olanzapine has activity both in the prevention of CINV in patients at high and moderate risk and in rescue treatment for patients with refractory nausea and vomiting. Studies have demonstrated its efficacy in preventing CINV in the setting of highly and moderately emetogenic chemotherapy. Newer, controlled trials show improved response rates when added to an antiemetic regimen of a 5-HT_3 antagonist plus dexamethasone as well as comparable activity to aprepitant.[27,39,42,43] The typical dose of olanzapine used in these trials was 10 mg PO daily on days 1 through 5.

Olanzapine is also active as a rescue agent for patients with refractory CINV. In this setting, the usual dose of olanzapine is 2.5 to 10 mg daily in one to four divided doses. The common side effects of olanzapine include sleepiness, dry mouth, and dizziness, although these were not significant in preliminary reports.[27,39,42,43] Olanzapine is an option for the prevention of CINV in patients receiving highly to

moderately emetogenic regimens and a good choice for control of highly refractory CINV symptoms.

OTHER ANTIEMETICS

Medications from other drug classes have also been used as antiemetics for CINV. These include dopamine antagonists (prochlorperazine, promethazine), benzodiazepines (lorazepam), butyrophenones (droperidol, haloperidol), benzamides (metoclopramide), and cannabinoids. Many of these agents were used widely until more effective antiemetic agents became available. These agents remain useful for breakthrough symptoms or for patients who are refractory to standard therapy. The dosages and indications for these agents are shown in Table 22-3. Many of these agents have more side effects than contemporary agents do, especially sedation and extrapyramidal side effects, such as dystonia and akathisia. Lorazepam is commonly used as a rescue antiemetic. Its mechanism of action as an antiemetic is not completely understood, but it may involve disruption of the cortical impulses to the VC, as well as anxiolytic activity.

Cannabinoids have long been used for refractory nausea and vomiting. This is based on the effect of the CNS cannabinoid receptors on the CTZ, the NTS, and the VC.[44] Small trials have shown conflicting effectiveness in the prevention of CINV.[45,46] An oral cannabinoid, nabilone, was approved for the treatment of CINV in patients who do not respond adequately to other antiemetics.[44] Cannabinoids are associated with side effects, such as drowsiness, dry mouth, dysphoria, vertigo, and euphoria.[44,45] Although some patients have a clear preference for, and good response to, cannabinoids, side effects and a lack of pronounced efficacy limit their use in the general population of chemotherapy patients. These agents are usually reserved for patients who do not have adequate relief from other rescue medications.

The optimal prophylactic antiemetic regimens depend on the emetic risk of the chemotherapy regimen. Treatment guidelines have been developed by several groups, including the American Society

of Clinical Oncology (ASCO; http://jco.ascopubs.org/content/24/18/2932.full.pdf+html)[16]; and the Multinational Association of Supportive Care in Cancer (MASCC; https://wwwnc.cdc.gov/travel/yellowbook/2020/travel-by-air-land-sea/motion-sickness).[17] These evidence- and consensus-based guidelines, which are similar in regard to the roles of the various antiemetics, are summarized in **Table 22-4** and **Figure 22-2**.

Table 22-4
Recommended Antiemetic Regimens for Chemotherapy-Induced Nausea and Vomiting by Emetogenicity of Chemotherapy Regimen

Emetogenicity Potential	Acute-Phase CINV (Doses Should Be Given 30–60 Minutes Before Chemotherapy) Day 1	Delayed-Phase CINV	Breakthrough CINV
High-risk IV chemotherapy regimens	**Four-Drug Regimen (Preferred)**		
	Olanzapine 5–10 mg PO once + NK1RA (select one) + 5-HT_3RA (select one) + dexamethasone 12 mg PO/IV once	Olanzapine 5–10 mg PO on days 2–4 + aprepitant 80 mg PO daily on days 2–3 (if aprepitant is the NK1RA used on day 1) + dexamethasone 8 mg PO/IV on days 2–4	Two agents for PRN use
	Three-Drug Regimen (Containing Olanzapine)		
	Olanzapine 5–10 mg PO once + palonosetron 0.25 mg IV once + dexamethasone 12 mg IV once	Olanzapine 5–10 mg PO daily on days 2–4	Two agents for PRN use
	Three-Drug Regimen (Containing NK1RA)		
	NK1RA (select one) + 5-HT_3RA (select one) + dexamethasone 12 mg PO/IV once	Aprepitant 80 mg PO daily on days 2–3 (if aprepitant is the NK1RA used on day 1) + dexamethasone 8 mg PO/IV on days 2–4	Two agents for PRN use
Moderate-risk IV chemotherapy regimens	**Three-Drug Regimen (Containing Olanzapine)**		
	Olanzapine 5–10 mg PO once + palonosetron 0.25 mg IV once + dexamethasone 12 mg PO/IV once	Olanzapine 5–10 mg PO daily on days 2–3	Two agents for PRN use
	Three-Drug Regimen (Containing NK1RA)		
	NK1RA (select one) + 5-HT_3RA (select one) + dexamethasone 12 mg PO/IV once	Aprepitant 80 mg PO daily on days 2–3 (if aprepitant is the NK1RA used on day 1) + dexamethasone 8 mg PO/IV on days 2–3	Two agents for PRN use
	5-HT_3RA + Dexamethasone		
	5-HT_3RA (select one) + dexamethasone 12 mg PO/IV once	Olanzapine 10 mg PO daily on days 2–3	Two agents for PRN use
Low-risk IV chemotherapy regimens	Single-dose dexamethasone or metoclopramide or prochlorperazine or 5-HT_3RA (ondansetron, granisetron, or dolasetron)	None	Either none or one agent for PRN use
Minimal-risk IV chemotherapy regimens	None	None	Usually none
High- to moderate-risk PO chemotherapy regimens	5-HT_3RA (ondansetron, granisetron, or dolasetron)	None	One agent for PRN use
Low-risk PO chemotherapy regimens	None	None	One agent for PRN use

5-HT_3RA, 5-hydroxytryptamine type 3 receptor antagonists; CINV, chemotherapy-induced nausea and vomiting; IV, intravenous; PO, oral; PRN, as needed; NK1RA, neurokinin 1 receptor antagonists.

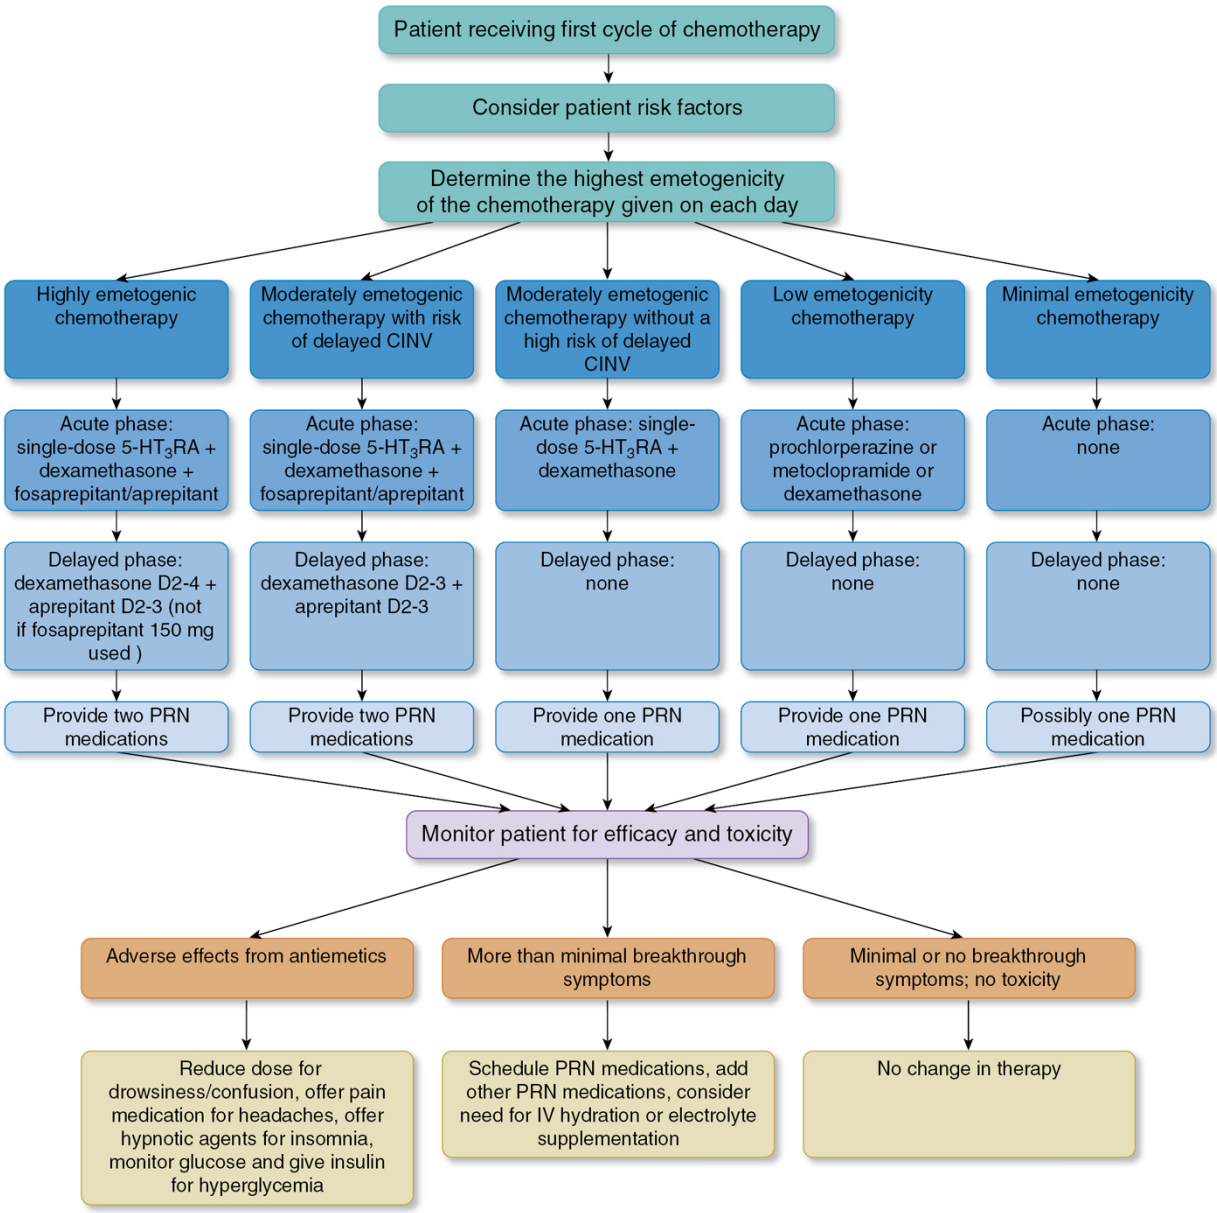

Figure 22-2 Algorithm for antiemetic selection of an *initial* chemotherapy cycle. 5-HT_3-RA, 5-hydroxytryptamine type 3 receptor antagonist; CINV, chemotherapy-induced nausea and vomiting; PRN, as needed.

Many patients may benefit from nondrug therapy for CINV symptoms, especially for anticipatory nausea and vomiting and anxiety. Techniques include guided imagery, hypnosis, relaxation techniques, systematic desensitization, and music therapy.[47] Acupuncture and acupressure techniques have been investigated for

use in CINV, and some patients benefit from their use. The use of acupressure devices that stimulate the P6 point on the wrist has been proposed; however, in a controlled trial in patients with breast cancer, it was not found to be helpful.[48] If patients are troubled by CINV symptoms, it is recommended that they refrain from heavy meals for 8 to 12 hours before chemotherapy. They should also avoid heavy, greasy foods and food with strong aromas. Chewing gum can mask the metallic taste that some patients perceive. Dry, salty foods can also help settle the stomach.

Clinical Presentation and Risk Factors

CASE 22-2

Question 1: M.C., a 54-year-old female with breast cancer, is in the clinic today to receive her first cycle of chemotherapy. Her chemotherapy will consist of docetaxel 75 mg/m^2 IV, carboplatin dosed to achieve an AUC of 6 mg/mL × minute. This will be repeated every 21 days. In addition, she will receive trastuzumab 4 mg/kg IV for one dose, then 2 mg/kg/week for 17 weeks. M.C. does not drink alcohol or smoke. Her only other medical condition is adult-onset diabetes, which is controlled with metformin and diet. She has had four children, now all grown, and had substantial morning sickness with each of her pregnancies. M.C.'s neighbor told her that all chemotherapy causes severe nausea and vomiting.

How likely is M.C. to experience nausea and vomiting? What are her risk factors?

M.C. is at moderate risk for acute CINV. Her personal risk factors include female sex, history of morning sickness with pregnancy, and being a nondrinker. The docetaxel has a low risk of acute CINV, the carboplatin has a moderate risk of acute CINV with a high risk of delayed CINV, and the trastuzumab has a minimal risk of acute CINV. A moderate-risk prophylactic regimen should be recommended for M.C.

Case 22-2, Question 2: What antiemetics are available for M.C.?

For moderate-risk prophylaxis, a two- to three-drug–containing regimen is recommended. For a single-day chemotherapy regimen, the aprepitant-containing regimen includes a single dose of 5-HT_3 antagonist plus dexamethasone 8 to 12 mg oral or IV plus oral aprepitant 125 mg on day 1, then oral dexamethasone 8 mg on days 2 through 4, and oral aprepitant 80 mg on days 2 and 3. The olanzapine-containing regimen includes olanzapine 10 mg oral on days 1 to 3, dexamethasone 20 mg IV once on day 1, and palonosetron 0.25 mg IV once on day 1. The two-drug–containing regimen includes a single dose of 5-HT_3 antagonist plus dexamethasone 8 to 12 mg oral on day 1, then dexamethasone 8 mg oral or IV daily on days 2 to 3, or 5-HT_3 antagonist monotherapy on days 2 and 3.

CASE 22-2, QUESTION 3: M.C. is at moderate risk for acute nausea and vomiting and at high risk for delayed CINV symptoms as a result of her chemotherapy regimen of docetaxel, carboplatin, and trastuzumab. What would be the most appropriate antiemetic regimen for M.C.?

For M.C., the best regimen would be a two- to three-drug–containing regimen. She should be offered medications for breakthrough CINV symptoms, such as prochlorperazine and lorazepam. She should be warned of the potential adverse effects of dexamethasone or olanzapine, especially hyperglycemia, and counseled to check her blood sugar levels more frequently and contact her physician if they remain elevated. M.C. should be advised to maintain a record of her symptoms and contact her physician if the breakthrough medications are not working or if she cannot keep fluids down.

If M.C. had been prescribed a multiday chemotherapy regimen, prophylaxis with a 5-HT_3 antagonist and dexamethasone should be offered for each day that moderately or highly emetogenic chemotherapy is administered.[1,16,17,49] If multiday chemotherapy regimens have a high risk of delayed symptoms, then therapy (eg, dexamethasone plus prochlorperazine or metoclopramide, if

aprepitant was already administered) for the delayed symptoms should be continued for at least 2 to 3 days after the last chemotherapy administration.

Modern antiemetic regimens achieve complete emetic control in about 70% to 90% of patients, but the response rate is lower for delayed CINV symptoms. If CINV symptoms are not adequately controlled, alterations in the prophylactic antiemetic regimen should be made for the next cycle (**Fig. 22-3**). Suggestions include upgrading to the next higher emetogenicity level recommendation, adding aprepitant if not already given, and scheduling antiemetic agents from other pharmacologic classes.

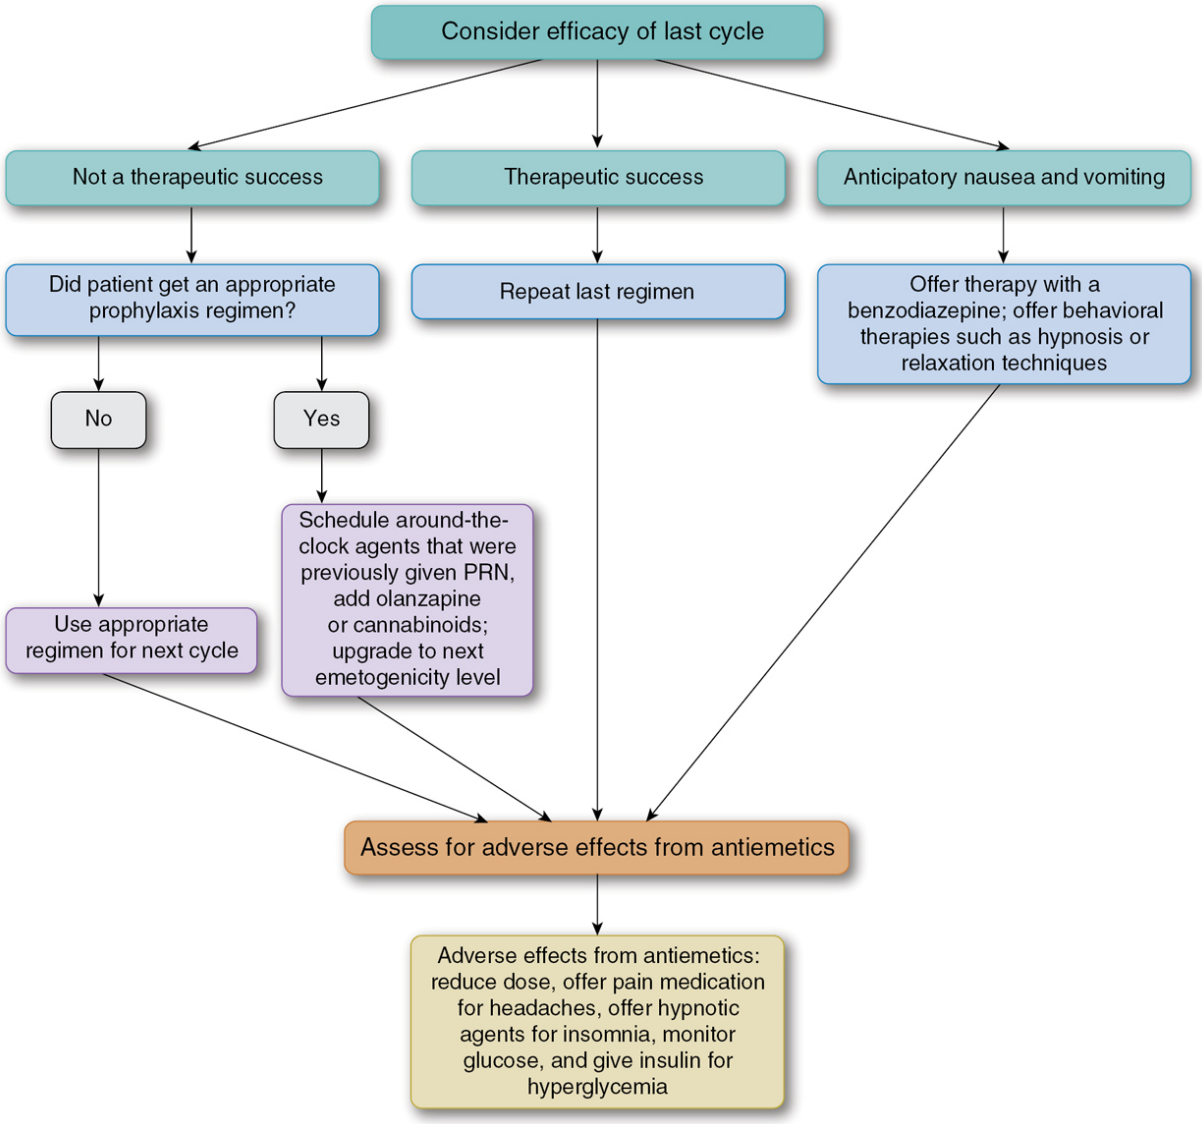

Figure 22-3 Algorithm for selection of antiemetic regimens for subsequent chemotherapy cycles. PRN, as needed.

RADIATION-INDUCED NAUSEA AND VOMITING

Clinical Presentation and Risk Factors

CASE 22-3

QUESTION 1: E.G. is a 54-year-old male with newly diagnosed head and neck cancer who will receive radiation therapy concurrently with cisplatin and fluorouracil chemotherapy. His daily (Monday through Friday) radiation treatments will last for 6 weeks. He has a heavy smoking history (35 pack-years) and "quit" last week, although it is not going well.

After nausea and vomiting from the chemotherapy subsides, is E.G. at risk for experiencing radiation-induced nausea and vomiting (RINV)? What antiemetic prophylaxis is appropriate?

Radiation therapy can cause nausea and vomiting through the same basic pathways that chemotherapy does. RINV affects 40% to 80% of patients receiving radiation therapy. The risk of RINV depends on several factors, namely, the size and area to be irradiated, larger fractional doses of radiation, and whether the patient has had previous chemotherapy.[1,50,51] Patients with radiation areas >400 cm^2 are more likely to have significant RINV symptoms. The radiation therapy oncologist will determine the size of the radiation field and fractional doses of radiation to maximize the efficacy of the radiation therapy. The high dose used in total body irradiation (associated with hematopoietic stem cell transplantation) causes RINV in >90% of patients. Patients receiving radiation to the upper abdominal area experience nausea and vomiting about 50% to 80% of the time. Radiation to other areas of the body is less likely to cause nausea and vomiting.

Overview of Treatment

Just as with CINV, symptoms caused by radiation can be prevented with 5-HT_3 antagonists, corticosteroids, or both. Evidence- and consensus-based recommendations have been published by several multidisciplinary groups, and are shown in **Table 22-5**. High-risk RINV is best treated with a combination of a 5-HT_3 antagonist and a corticosteroid.[1,50-53] Patients receiving concomitant chemotherapy and radiation should receive antiemetics appropriate for the chemotherapy regimen.[1] Patients receiving radiotherapy in the moderate RINV risk group can receive either prophylaxis or rescue therapy with a 5-HT_3 antagonist.

Table 22-5
Prophylaxis for Radiation-Induced Nausea and Vomiting for Adults

Emetic Risk	Radiation Area	Recommendation
High risk	Total body irradiation	Prophylaxis with a 5-HT_3RA (eg, ondansetron 8 mg PO bid–tid or granisetron 2 mg PO daily) ± dexamethasone 4 mg PO daily
Moderate risk	Upper abdomen	Prophylaxis with a 5-HT_3 antagonist (eg, ondansetron 8 mg PO bid or granisetron 2 mg PO daily) ± dexamethasone 4 mg PO daily

5-HT_3RA, 5-hydroxytryptamine type 3 receptor antagonist; bid, twice daily; PO, oral; tid, three times daily.

Evaluation of new antiemetic agents and definition of antineoplastic agent emetogenicity—an update. *Support Care Cancer*. 2005;13:80–84; Roila F, Herrstedt J, Aapro M, et al. Guideline update for MASCC and ESMO in the prevention of chemotherapy- and radiotherapy-induced nausea and vomiting: results of the Perugia consensus

conference. *Ann Oncol*. 2010;21(Suppl 5):v232–v243; Feyer P, Maranzano E, Molassiotis A, et al. Radiotherapy-induced nausea and vomiting (RINV): MASCC/ESMO guideline for antiemetics in radiotherapy: update 2009. *Support Care Cancer*. 2011;19 Suppl 1:S5-S14; Abdelsayed GG. Management of radiation-induced nausea and vomiting. *Exp Hematol*. 2007;35(4 Suppl 1):34–36.

Although E.G. is receiving concurrent chemotherapy, he is at low risk for experiencing RINV because his radiation site will be in the head and neck region, it is not likely to be >400 cm^2, and he will likely receive a smaller fractional dose. Because E.G. is at low risk for having RINV symptoms, he does not need prophylaxis with a 5-HT_3 antagonist. If he experiences symptoms, rescue therapy with a dopamine antagonist or a serotonin antagonist should be offered.

POSTOPERATIVE NAUSEA AND VOMITING

Clinical Presentation and Risk Factors

CASE 22-4

QUESTION 1: E.W. is a 48-year-old female who is scheduled for a laparoscopic cholecystectomy. The scheduled duration of her surgery is less than an hour. Her medical history includes hypertension. She does not have a history of motion sickness and is a nonsmoker. E.W. has never had surgery before. Her sister-in-law had severe nausea and vomiting after an outpatient surgical procedure last year, and E.W. is worried that she too may have it.

What is E.W.'s risk of having postoperative nausea and vomiting (PONV)? What can be done to reduce her risk, and how can symptoms be treated if they occur?

PONV is a common complication of surgery affecting 25% to 30% of all patients, but up to 80% of patients in high-risk groups.[54] In surgical patients, PONV can lead to hospitalizations, stress on the surgical closure, hematomas, and aspiration pneumonitis. Patient-related, surgical, and anesthetic factors can increase the risk of PONV.[54–58] Patient risk factors include female sex, history of motion

sickness, nonsmoking status, age younger than 50 years, and a history of PONV.[11] Some surgical risk factors for PONV include type of surgical procedure (eg, laparoscopy, gynecologic surgeries, intra-abdominal surgery, and neurosurgery) and prolonged surgical time.[11] Anesthesia-related risk factors include the use of volatile anesthetics, nitrous oxide, prolonged duration of anesthesia, increased doses of neostigmine (>3 mg), and the use of intraoperative or postoperative opioids.[11] Children are twice as likely to have PONV as do adults, but the risk declines after puberty.[55,59]

Certain anesthesia practices may reduce the risk of PONV. These include use of regional anesthesia (instead of general anesthesia); use of total IV anesthesia with propofol; use of intraoperative oxygen; adequate hydration; and avoidance of nitrous oxide, volatile anesthesia therapy, and intraoperative or postoperative opiates.[54–56,58–60] Using propofol for anesthesia (or sedation) is associated with a 3.5-fold reduction in the incidence of PONV in adults and 5.7-fold reduction in children.[11]

Antiemetics to treat nausea and vomiting produce major side effects ranging from mild headache to severe arrhythmia due to QTc prolongation. Therefore, it is essential to calculate the risk of developing PONV and post discharge nausea and vomiting (PDNV) in each patient to reduce excessive use of antiemetics for prophylaxis.[11] Several risk factor models have been studied to correlate these factors into recommendations for prevention and therapy.[54,56] One model, the Apfel risk scoring system, is both simple and practical. A study by White et al[61] reported that an Apfel risk score of 3 or 4 (vs a score of 1–2) is associated with a higher incidence of emesis in the first 24 hours after surgery irrespective of administration of multiple antiemetics as prophylaxis.[11] This model uses the following risk factors: biologic sex, history of PONV or motion sickness, smoking status, and the use of postoperative opioids.[11] The PONV risk increases by 10%, 21%, 39%, 69%, and 79% when 0, 1, 2, 3, and 4 factors are present, respectively. Apfel's risk scoring system is more sensitive and specific compared to predicting PONV based on history of PONV or type of surgery alone. E.W. has at least two risk factors (female, nonsmoker) that may

increase if her surgery lasts longer than expected, or if she receives intraoperative or postoperative opioids. She has a moderate to high risk of PONV.

The Apfel risk scoring system is not directly applicable to children. Instead, the Eberhart classification scoring system is more often used for children and incorporates the following risk factors: age older than 3 years, duration of surgery >30 minutes, strabismus surgery, and personal or family history of PONV.[11] The risk of PONV for children undergoing strabismus surgery with 0 to 1, 2, 3, or 4 of these risk factors is 10%, 30%, 50%, and 70%, respectively.[11] This scoring system has also been validated for children having surgery other than for strabismus, and PONV was observed in 3%, 11%, 30%, and 40% of children who had 0, 1, 2, or 3 risk factors, respectively.

Overview of Treatment

The management strategy for each individual patient should be based on the level of risk for PONV, the patient's preexisting condition, patient preference, and cost efficiency.[11] Patients with zero or one risk factor typically will not need prophylaxis. Patients with moderate risk (two to three risk factors) should receive one to two antiemetics. Appropriate choices for monotherapy include droperidol, a 5-HT_3 antagonist, or dexamethasone. Patients at the highest risk for PONV (at least four risk factors) should be given prophylaxis with a combination of two to three antiemetics. Dual-therapy choices include a 5-HT_3 antagonist plus either droperidol or dexamethasone. Triple therapy would combine a 5-HT_3 antagonist plus dexamethasone plus droperidol. Because E.W. has a moderate to high risk for PONV, a combination of a 5-HT_3 antagonist (such as ondansetron 4–8 mg at the end of surgery) and dexamethasone (4–10 mg after induction of anesthesia)[11] would be a good choice for prophylactic therapy.

The most effective and commonly used medications for the prevention of PONV include 5-HT_3 antagonists, dexamethasone,

droperidol, and combinations of these agents. 5-HT_3 antagonists have differences regarding its efficacy and duration of action. Granisetron, a more selective 5-HT_3 antagonist, has been suggested to provide more sustained antiemesis for prophylaxis.[62] Ramosetron has a greater affinity for the 5-HT_3 receptor and a longer duration of antiemetic action. This results in a similar or greater prophylactic antiemetic effect than that of the older 5-HT_3 receptor antagonists (eg, ondansetron), and provides better antiemetic efficacy in patients at moderate to high risk.[11] Droperidol has long been used for PONV, but concerns have been raised about the rare occurrence of QTc prolongation and torsades de pointes.[63,64] Most clinicians believe droperidol to be safe, especially when doses are not excessive (up to 1.25–2.5 mg/dose for adults).[55,64,65] Multiple well-controlled, randomized, comparative clinical trials have validated droperidol to be as safe and effective than are the more costly 5-HT_3 and NK1 antagonists.[66,67] The mechanism by which dexamethasone protects against PONV is unclear, but its efficacy has been shown in many trials.[55,59,63] Ormel et al found that dexamethasone 4 to 5 mg was equally as effective as 8 to 10 mg in terms of antiemetic efficacy.[68] Combinations of medications with different mechanisms of action are more effective than is monotherapy. Aprepitant has been studied in the prevention of PONV.[32,54,55] Studies have shown similar activity of aprepitant compared with ondansetron.[32,54,55] Aprepitant, however, is significantly more expensive than is generic ondansetron or dexamethasone, which is a consideration. The use of aprepitant is also limited by the potential for drug interactions.[58] Dexamethasone and 5-HT_3 antagonist combinations have been well studied and are highly effective.[54,55,59,63,65] Transdermal scopolamine is also effective, but can have side effects.[54] Dosages for the prophylaxis and treatment of PONV are shown in **Table 22-6**. The 5-HT_3 antagonists and droperidol seem to be more effective when given at the end of surgery. Corticosteroids are best given after the induction of anesthesia.[11] Although not a first-line agent, the dopamine (D_2) receptor antagonist amisulpride (Barhemsys®) has been found to be

effective in treating PONV after failed prophylaxis[69] for patients at low-to-moderate risk of PONV who received no prior PONV prophylaxis.[70]

Table 22-6
Prophylactic Doses and Timing for the Administration of Antiemetic Drugs

Drug Group	Drugs	Dose	Timing	Adverse Effect
Serotonin (5-HT_3 receptor) antagonists	Ondansetron	4–8 mg IV every 4–8 hours	End of surgery	Headaches, constipation, flushing, fatigue, malaise, raised liver enzymes
	Granisetron	1–2 mg IV		
	Ramosetron	0.3 mg IV 0.1 mg PO		
	Palonosetron	0.075–0.25 mg IV		
Corticosteroids	Dexamethasone	4–10 mg IV	After induction of anesthesia	Elevated blood glucose level, diabetes mellitus, hypotension/hypertension
Butyrophenone	Droperidol	0.625–1.25 mg IV	After induction of anesthesia	Psychomimetic effects, extrapyramidal side effects, Parkinson disease, sedation, lightheadedness, prolonged QT interval
Neurokinin antagonists (NK-1 receptors)	Aprepitant	40 mg orally	1–2 hours before induction	Headaches, constipation, fatigue
	Fosaprepitant	150 mg IV	After induction of anesthesia	
Anticholinergics	Scopolamine	Transdermal patch[a] 1.5 mg for 24 hours	Evening before[a] surgery or at least 1–2 hours before operation	Dizziness, dry mouth, visual disturbances, tachycardia, confusion, urinary retention
Dopamine antagonists	Metoclopramide	10–25 mg IV	15–30 minutes before end of surgery	Sedation, hypotension (fast injection), headache, extrapyramidal symptoms
	Amisulpride IV	5–10 mg IV	At induction of anesthesia	

IV, intravenous; PO, oral.

Ginger root contains the active ingredients gingerol (Ginjervel) and shogaol (Chagall). They reduce stomach contractions and increase GI tract motility via anticholinergic and antiserotonergic actions.[11] There has been conflicting information reported concerning the effectiveness, but it may be an option for E.W.

Nonpharmacologic techniques for the prevention of PONV have been studied and shown to be effective in some patient populations. These include acupuncture, transcutaneous nerve stimulation,

acupressure at the P6 wrist point, hypnosis, and aromatherapy with isopropyl alcohol.

Even with appropriate prophylaxis for PONV, some patients will experience breakthrough symptoms and require rescue therapy.[54] Patients who have not received prophylaxis with a 5-HT_3 antagonist can be offered it as rescue therapy. Only one-quarter of the typical 5-HT_3 prophylaxis dose is needed.[55] For all patients who have breakthrough symptoms, it is important to choose an antiemetic from a different pharmacologic class than the agents used for prophylaxis.[54,56,63] Droperidol, promethazine, metoclopramide, and prochlorperazine are commonly used as rescue medications. If E.W. had breakthrough nausea, droperidol (0.625–1.25 mg IV or intramuscular every 4–6 hours as needed) would be a good choice for rescue therapy.

Upper Gastrointestinal Disorders

Elaine J. Law and Ricky B. Thumar

CORE PRINCIPLES	CHAPTER CASES
PEPTIC ULCER DISEASE	
1 Chronic peptic ulcer disease (PUD) is causally linked to *Helicobacter pylori* infection or the use of nonsteroidal anti-inflammatory drugs (NSAIDs), and is usually characterized by epigastric pain or discomfort, sometimes accompanied by heartburn, bloating, and belching.	**Case 23-1 (Questions 1, 2) Case 23-2 (Question 1) Case 23-4 (Question 3)**

CORE PRINCIPLES		CHAPTER CASES
2	Treatment for PUD is aimed at relieving ulcer symptoms, healing the ulcer, eradicating *H. pylori* (if finding is positive), preventing ulcer recurrence, and reducing ulcer-related complications; eradication is recommended for all patients with an *H. pylori*–positive active ulcer or a history of a previous ulcer or ulcer-related complication; proton-pump inhibitors (PPIs) are the drugs of choice for healing and reducing the risk of an NSAID ulcer; patients with a peptic ulcer should be recommended lifestyle modifications.	**Case 23-1 (Questions 3–10) Case 23-2 (Questions 2–10)**
3	Treatment for an *H. pylori* ulcer should be initiated with a clarithromycin-based three-drug eradication regimen; the regimen should be effective, well tolerated, easy to comply with, cost-effective, and should take into consideration antibiotic resistance; if a second course of therapy is necessary, it should contain different antibiotics.	**Case 23-1 (Questions 3, 4, 6–10)**

CORE PRINCIPLES		CHAPTER CASES
4	PPIs are the preferred agents for healing an *H. pylori*–negative NSAID ulcer because they accelerate ulcer healing and provide more effective symptom relief than do histamine-2 receptor antagonists (H_2RAs); the duration of treatment should be extended if the NSAID is continued; if the patient is *H. pylori* positive, a clarithromycin-based three-drug regimen should be used.	**Case 23-2 (Questions 2, 3, 10)**
5	Prophylactic risk reduction therapy with a PPI or misoprostol or switching to an NSAID with greater cyclooxygenase-2 (COX-2) selectivity is recommended for patients at risk for exhibiting an ulcer or ulcer-related complication; when selecting a PPI, its gastrointestinal benefits must be weighed against the cardiovascular risks associated with COX-2 inhibitors and concomitant antiplatelet therapy.	**Case 23-2 (Questions 4–7) Case 23-5 (Question 2)**
6	Patients receiving an *H. pylori* eradication regimen, those undergoing treatment for an active NSAID ulcer, and individuals receiving prophylactic risk reduction therapy require patient education regarding ulcer risk, potential ulcer complications, and drug therapy.	**Case 23-1 (Question 5) Case 23-2 (Questions 8, 9)**

GASTROESOPHAGEAL REFLUX DISEASE

CORE PRINCIPLES		CHAPTER CASES
1	The classic symptoms associated with gastroesophageal reflux disease (GERD) are usually very specific and include heartburn and acid regurgitation; however, not all patients will present with these typical symptoms and may present with more serious “alarm symptoms” or extra esophageal manifestations, warranting referral for further evaluation.	**Case 23-3 (Question 1)**
2	Appropriate management of the patient with GERD is focused on the relief of symptoms, promotion of healing of the esophageal mucosa, and prevention of relapse or the development of complicated disease. This is accomplished with lifestyle modification and pharmacotherapy directed at reducing esophageal mucosal exposure to gastric acid.	**Case 23-3 (Questions 2–4)**
3	Diagnostic testing strategies for patients with more severe GERD include empiric acid suppression test, upper endoscopy and biopsy (in the presence of alarm symptoms), ambulatory esophageal reflux monitoring, and esophageal manometry.	**Case 23-4 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
4	Mild-to-moderate GERD can be managed acceptably with antacids, sucralfate, and H_2RAs; however, for more severe, frequent, or complicated GERD, the drugs of choice are PPIs, which have demonstrated superiority over these other agents in terms of symptom relief and esophageal healing.	**Case 23-4 (Question 2)**
5	GERD can be associated with numerous manifestations that occur outside the esophagus, including noncardiac chest pain, asthma, hoarseness, laryngitis, and chronic cough.	**Case 23-5 (Question 1)**
UPPER GASTROINTESTINAL BLEEDING		
1	Stress-related mucosal bleeding (SRMB) is a serious complication that can occur in critically ill patients under severe physiologic stress. Appropriate prophylactic management includes identification of risk factors for SRMB, such as mechanical ventilation and coagulopathy, and then implementation of an appropriate pharmacotherapy strategy (eg, PPIs, H_2RAs) aimed at reducing the risk of exhibiting SRMB.	**Case 23-6 (Questions 1–4)**

INTRODUCTION

Upper gastrointestinal (GI) disorders are a subset of GI diseases that vary in severity from simple discomfort to life-threatening illness, and include dyspepsia, peptic ulcer disease (PUD), gastroesophageal reflux disease (GERD), Zollinger–Ellison syndrome (ZES), and upper GI bleeding. Most are acid related, whereby gastric acid plays an important role in their development, progression, and treatment. Common pharmacotherapeutic options include antacids, histamine-2 receptor antagonists (H_2RAs), and proton-pump inhibitors (PPIs).

Total annual U.S. health care expenditures for all GI diseases ($135.9 billion) exceed those for heart disease ($113.4 billion), trauma-related disorders ($102.7 billion), and mental disorders ($98.8 billion); of those expenditures, upward of $12.4 billion is spent on prescription H_2RAs and PPIs.[1] Management and treatment of these diseases place a substantial burden on both patients and the health care system.

PHYSIOLOGY OF THE UPPER GASTROINTESTINAL TRACT

The upper GI tract consists of the mouth, esophagus, stomach, and duodenum (**Fig. 23-1**). Ingested food or liquids pass from the mouth through the esophagus and into the stomach. As these substances enter into the esophagus, the lower esophageal sphincter (LES), an area of smooth muscle near the distal end of the esophagus, relaxes to allow their entry into the stomach. The LES usually remains contracted to prevent the reflux of gastric contents into the esophagus. However, peristaltic contractions of the esophageal muscles allow the LES to remain open until all food has entered the stomach.[2]

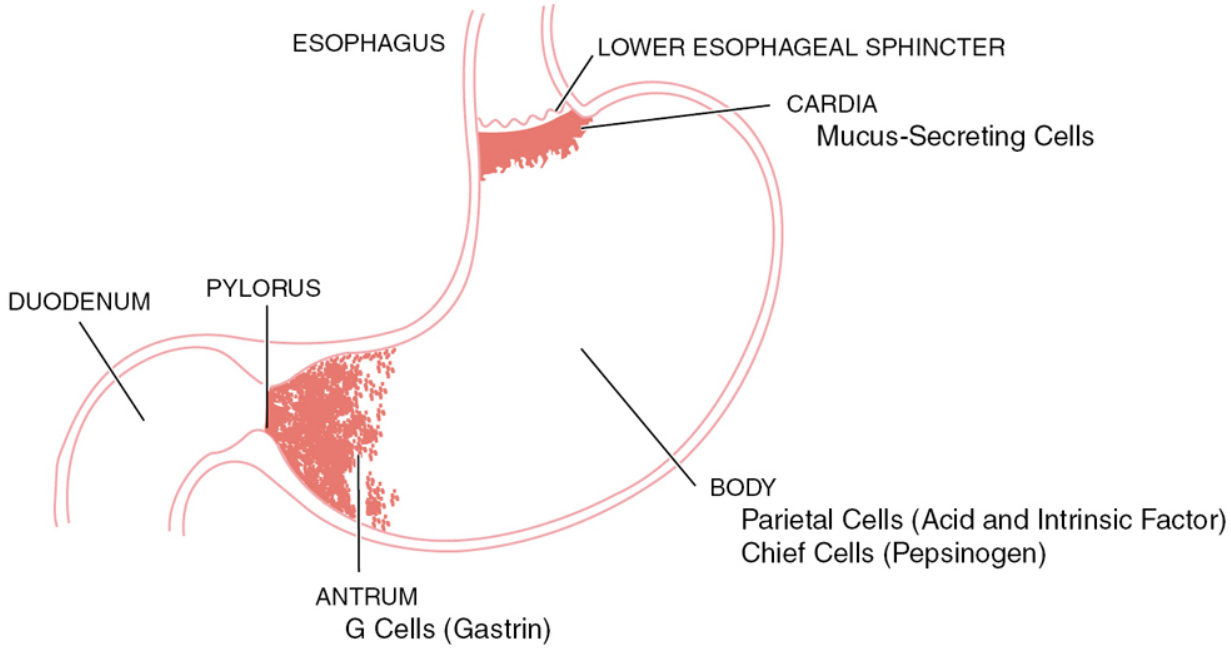

Figure 23-1 Gastrointestinal anatomic regions.

The stomach consists of three distinct anatomic regions, each responsible for a variety of specialized functional processes (see Fig. 23-1). The cardia is the uppermost portion of the stomach (~5% of its surface area), and is responsible for the mucous secretion that protects against the stomach's acidic environment. The body of the stomach makes up the majority of its surface area (80%–90%) and contains parietal cells, which secrete gastric acid and intrinsic factor, as well as peptic (chief) cells, which secrete pepsinogen. Intrinsic factor is required for vitamin B_{12} absorption. Under acidic conditions in the stomach, pepsinogen is converted to pepsin, which is a proteolytic enzyme responsible for breaking down protein. The antrum is the lower portion of the stomach (10%–20% of its surface area) and contains G cells which secrete gastrin. The final portion of the upper GI tract is the duodenum, which begins just after the pylorus and extends to the ligament of Treitz (at which point the jejunum begins the first portion of the lower GI tract).

Three stimuli (neurologic, physical, and hormonal) trigger the parietal cell to secrete gastric acid. Neurologic impulses, from the central nervous system (CNS) and initiated by the sight, smell, and taste of food, travel along cholinergic pathways to stimulate the

release of acetylcholine, which arrives via nerve endings and activates the muscarinic receptor on the parietal cell.[3] Ingested food causes gastric distension, which triggers the release of acetylcholine and also stimulates G cells within the antrum to produce gastrin. Elevated intragastric pH also stimulates the production of gastrin; low gastric pH provides a feedback mechanism to inhibit its production. The stomach is also protected from overproduction of gastric acid by the release of somatostatin from antral D cells, which signals the G cells to stop the production of gastrin.[3] Gastrin enters the blood and arrives at the parietal cell, where it binds to the gastrin receptor. Acetylcholine and gastrin promote the release of histamine from the mast cell or enterochromaffin- like (ECL) cells, which then binds to the histamine H_2 receptor on the parietal cell. Histamine release is associated with both postprandial and nocturnal acid secretion.

The gastrin, histamine H_2, and muscarinic receptors are located on the basolateral membrane of the parietal cell (**Fig. 23-2**). Activating any of these receptors leads to a cascade of events that increase and activate intracellular protein phosphokinases. This, in turn, activates the hydrogen–potassium adenosine triphosphatase (H^+/K^+-ATPase) pump, better known as the *proton pump*. The proton pump is an ion transport pathway that transports hydrogen ions out of the cytoplasm, in exchange for potassium ions, and into the secretory canaliculus of the parietal cell. Here, the hydrogen ions combine with chloride from the blood to form hydrochloric acid, which is then released into the gastric lumen. The proton pump is the final common pathway for gastric acid secretion.[3]

Pharmacology: The Pathophysiologic Basis of Drug Therapy. 3rd ed. Wolters Kluwer Health/Lippincott Williams & Wilkins; 2011.)

PHARMACOTHERAPY OF DRUGS USED TO TREAT ACID-RELATED DISORDERS

The following section briefly reviews the drugs used to treat acid-related disorders (**Table 23-1**). Their therapeutic use is discussed under each specific GI disorder.

Table 23-1
Oral Medications Used to Treat Upper Gastrointestinal Disorders

	Gastric and Duodenal Ulcer Healing	Maintenance of Gastric and Duodenal Ulcer Healing	Reduction of Gastric Ulcer Risk Associated With NSAIDs	Relief of Heartburn and Indigestion (OTC Use)	Relief of GERD Symptoms (Rx Use)	Esophageal Healing[a]	Maintenance of Esophageal Healing[a]	Hypersecretory Diseases[a,b]
H_2 Receptor Antagonists								
Cimetidine	300 mg qid	400–800 mg at bedtime	Not indicated	200 mg bid prn	300 mg qid	400 mg qid	400–800 mg at bedtime	[a]
	400 mg bid					800 mg bid		
	800 mg daily							
Famotidine	20 mg bid	20–40 mg at bedtime	Not indicated	10 mg bid prn	20 mg bid	40 mg bid	20–40 mg bid	[a]
	40 mg at bedtime			20 mg bid prn				
Nizatidine	150 mg bid	150–300 mg at bedtime	Not indicated	75 mg bid prn	150 mg bid	300 mg bid	150–300 mg bid	[a]
	300 mg at bedtime							
Ranitidine	150 mg bid	150–300 mg at bedtime	Not indicated	75 mg bid prn	150 mg bid	300 mg bid	150–300 mg bid	[a]
	300 mg at bedtime			150 mg bid prn				
Proton-Pump Inhibitors								
Esomeprazole	20–40 mg daily	20 mg daily	20 mg daily	20 mg daily[c]	20 mg daily	20–40 mg daily	20 mg daily	40 mg bid
Dexlansoprazole	Not indicated	Not indicated	Not indicated	Not indicated	30 mg daily	60 mg daily	30 mg daily	Not indicated
Lansoprazole	15–30 mg daily	15–30 mg daily	15–30 mg daily	15 mg daily[c]	15–30 mg daily	30 mg daily	15–30 mg daily	60 mg daily
Omeprazole	20 mg daily	20 mg daily	20 mg daily	20 mg daily[c]	20 mg daily	20–40 mg daily	20 mg daily	60 mg daily
Pantoprazole	40 mg daily	40 mg daily	40 mg daily	Not indicated	20 mg daily	40 mg daily	40 mg daily	80 mg daily
Rabeprazole	20 mg daily	20 mg daily	20 mg daily	Not indicated	20 mg daily	20 mg daily	20 mg daily	60 mg daily
Other Agents								
Sucralfate	1 g qid	Not indicated	Not indicated	Not indicated	Not indicated	Not indicated	Not indicated	Not indicated
	2 g bid							
Misoprostol	Not indicated	Not indicated	200 μg tid–qid	Not indicated	Not indicated	Not indicated	Not indicated	Not indicated

bid, two times daily; qid, four times daily; tid, three times daily.

[a]Although U.S. Food and Drug Administration (FDA) labeled for this indication, H_2 receptor antagonists (H_2RAs) are not recommended because they are not as effective as the proton-pump inhibitors (PPIs).

[b]Initial starting dose; daily dosage must be titrated to gastric acid–secretory response.

[c]Duration of treatment should not exceed 14 consecutive days; if needed, repeat 14-day treatment every 4 months.

Antacids

Antacids are available over the counter (OTC) and widely used to relieve mild and infrequent GI symptoms. They work by partially neutralizing gastric acid, thus increasing gastric pH and inhibiting pepsin. Options include salts or combinations of calcium, magnesium, aluminum, or sodium salts.[4] Because their therapeutic and adverse effects are dose dependent and large doses are required to raise gastric pH, their value in certain acid-related GI disorders has diminished with the advent of H_2RAs and PPIs. Their effect is quick in onset (within minutes), but relatively short in duration (up to 1 hour on an empty stomach; up to 3 hours with or 1 hour after a meal).[4] Beyond their acid-neutralizing capacity, antacids have mechanisms by which they benefit other GI and non-GI disorders, which are discussed elsewhere.[4]

Antacids are generally well tolerated. When used alone, magnesium-containing antacids may cause a dose-related osmotic diarrhea, whereas aluminum- and calcium-containing antacids may cause constipation. Aluminum is often coformulated with magnesium to offset the diarrhea (which still predominates at higher doses of the combination).[4,5] Antacid use in renal insufficiency warrants caution. Small amounts of aluminum and magnesium are absorbed systemically and have the potential to accumulate in patients with renal insufficiency and lead to toxicity. As such, magnesium-containing antacids should be avoided in patients with a creatinine clearance <30 mL/minute; and chronic use of aluminum-containing antacids should be avoided in patients with renal failure.[4,5] Hypercalcemia from calcium carbonate has been described in patients with renal failure taking as little as 4 g/day; patients with normal renal function generally are at lower risk unless using prolonged, large doses (>20 g/day).[4] Sodium bicarbonate should not be used for long periods of time (especially in renal impairment) because systemic alkalosis can result from the accumulation of

bicarbonate. Further, the high sodium content (274 mg sodium per gram sodium bicarbonate) has been associated with sodium retention, and may pose a problem in patients with hypertension, ascites, severe renal dysfunction, or heart failure.[4,5]

Drug interactions must also be considered with antacids. Because all of them change gastric pH, they can reduce acid hydrolysis of drugs, alter dissolution of drug dosage forms, or reduce urinary pH and thus alter elimination. Apart from sodium bicarbonate, antacids can also decrease absorption of other drugs through chelation.[4,6] Orally administered drugs that require an acidic environment for dissolution and absorption (eg, digoxin, phenytoin, isoniazid, ketoconazole, itraconazole, iron preparations) will have reduced bioavailability when improperly used with antacids, leading to potential therapeutic failures. An increase in gastric pH may also prematurely break down the enteric coating of relevant dosage forms because the coating is usually designed to dissolve at a higher pH than does gastric acid.[5,6] Urinary alkalinization may result in either increased urinary excretion (eg, salicylates) or decreased excretion (eg, amphetamines and quinidine), leading to decreased or increased blood concentrations, respectively.[4–6] Certain drugs (eg, tetracyclines, fluoroquinolones, levothyroxine) can bind/chelate with calcium, aluminum, or magnesium (as divalent and trivalent cations) to form an insoluble and inactive complex, thereby reducing bioavailability.[5,6] Almost all of these drug interactions can be avoided by separating the antacid from the interacting drug by a minimum of 2 hours.[5,6]

Histamine-2 Receptor Antagonists

The four H_2RAs approved for use in the United States include famotidine, ranitidine, nizatidine, and cimetidine, with varying prescription and OTC availability as well as differences in oral and parenteral formulations. They competitively and selectively inhibit the action of histamine on the H_2 receptors of the parietal cells, thus reducing both basal and stimulated gastric acid secretion (Fig. 23-2).

Standard oral doses across the class have been adjusted to account for varying potency within the class, whereby each H_2RA has approximately equipotent antisecretory effects (Table 23-1).[7] Compared to antacids, onset of symptom relief with H_2RAs is not as rapid (30–45 minutes), although duration of effect is longer (4–10 hours).[5] The oral bioavailability of nizatidine is considered nearly 100% because this agent does not undergo first-pass metabolism; cimetidine, famotidine, and ranitidine undergo first-pass metabolism, resulting in 40% to 65% bioavailability. All four drugs are eliminated by a combination of hepatic metabolism, glomerular filtration, and tubular secretion.[7,8] Hepatic metabolism is the principal pathway for the elimination of cimetidine, famotidine, and ranitidine, whereas renal excretion is the major route for elimination of nizatidine.[7–9] The pharmacokinetics appear to be unaffected by hepatic dysfunction; however, in patients with combined hepatic failure and renal insufficiency, dose reduction is likely necessary.[9] Dose reductions for all four agents are recommended for patients with moderate-to-severe renal insufficiency.[5]

H_2RAs are well tolerated with low incidence of mostly nonspecific adverse effects (ie, headache, diarrhea, constipation, dizziness, and drowsiness). Cimetidine has been shown to have a mild antiandrogenic effect, whereby high doses may result in decreased libido, impotence, or gynecomastia in males; this is reversible upon discontinuation, and has not been shown with famotidine, ranitidine, or nizatidine.[5,10] Although rare and also reversible upon discontinuation, thrombocytopenia may occur with any of the four H_2RAs; although more commonly reported with intravenous (IV) administration, it is likely that the overall incidence of H_2RA-associated thrombocytopenia is overestimated.[11,12] Hepatotoxicity, although uncommon, has also been described, but primarily in patients receiving IV H_2RAs.[13] Patients at highest risk for experiencing any of these adverse effects include the elderly, those requiring higher doses (usually parenteral), and those with altered renal function.[10,14]

Similar to antacids, all four H_2RAs can potentially alter the absorption and reduce the bioavailability of drugs that require an acidic environment for absorption. Taking into account the longer time to peak effect as well as longer duration of effect with H_2RAs as compared to antacids, various mitigation strategies can be considered including avoidance, monitoring change in effects, and possible dose adjustments.[6] Of the four, cimetidine has the greatest potential to cause drug interactions because of its ability to inhibit several hepatic cytochrome P-450 (CYP450) isozymes, including CYP1A2, CYP2C19, CYP2D6, and CYP3A4.[6] Ranitidine is less inhibitory than is cimetidine, and thus has less interaction concerns, whereas famotidine and nizatidine do not bind appreciably to the CYP450 system and do not interact with drugs that are metabolized through this hepatic system.[6] Organic cation transporters (OCTs) in the kidney support drug excretion. Not only can H_2RAs inhibit these transporters, specifically OCT2, but they can also compete with other drugs that use OCTs to undergo renal tubular excretion, resulting in reduced drug excretion.[6,15,16] Tachyphylaxis, or tolerance, to the antisecretory effect has been described with all H_2RAs, and appears to occur more frequently with high-dose parenteral formulations as well as daily (vs as-needed) oral use.[6,14,17,18]

Reports of contaminants in various medications have been on the rise in recent years, prompting inquiry, investigation, and action by the U.S. Food and Drug Administration (FDA). The contaminants seem related to excipient and/or manufacturing rather than to the actual medications, but investigations are ongoing. One of the main contaminants in question is N-Nitrosodimethylamine (NDMA), which is considered a probable human carcinogen. With ranitidine being implicated, the FDA has requested manufacturers to withdraw all prescription and OTC products from the market as of April 1, 2020.[19] At the time of this writing, the investigation is still ongoing, and other H_2RAs have not been implicated.

Proton-Pump Inhibitors

PPIs are highly specific inhibitors of gastric acid secretion, and include omeprazole, lansoprazole, rabeprazole, pantoprazole, esomeprazole, and dexlansoprazole. These agents act by irreversibly binding to the aforementioned H^+/K^+-ATPase (proton pump). PPIs are the most potent inhibitors of gastric acid secretion in that they inhibit the terminal step in the acid production cycle.[20–22] They inhibit both basal and stimulated gastric acid secretion in a dose-dependent and sustained manner.[21] Despite most of them having short plasma elimination half-lives (~1–2 hours), their antisecretory effect lasts 48 to 72 hours because of covalent (irreversible) binding to the proton pump.[22,23] PPIs are prodrugs that require an acidic environment for conversion to the active moiety. They are absorbed in the small intestine (protected from the acidic milieu of the stomach by enteric coating) and taken via the bloodstream to the acidic secretory canaliculus of the parietal cell for protonation to the active form (**Fig. 23-2**).[20,22] This conversion requires an actively secreting proton pump; thus, PPIs are most efficacious when taken 30 to 60 minutes before a meal.[22] Of note, although it does not suggest clinical superiority to other PPIs, dexlansoprazole uses a unique dual delayed- release technology that extends the duration of its antisecretory effect, thus allowing it to be taken without regard to meal times.[24]

Although the benefits and risks with PPI use are mostly the same across the class when used in equivalent doses (**Table 23-1**), PPIs are superior to H_2RAs in reducing gastric acid secretion and improving mucosal healing.[23,25–31] Dose reduction is not required in patients with renal insufficiency, but is recommended for patients with severe hepatic impairment due to reduced clearance.[32] All PPIs are available for oral use as tablets, capsules, disintegrating tablets, or oral suspensions and via slightly differing technologic mechanisms of drug absorption/delivery.[25] The immediate-release formulation of omeprazole contains sodium bicarbonate, requiring precautions as noted in the section on Antacids of this chapter. Only pantoprazole and esomeprazole are available for IV use in the United States; oral options may be prescription or OTC, although

specific dosage forms or compounding options are also available (**Table 23-12**; see section on Upper Gastrointestinal Bleeding).

Drug interaction profiles for PPIs warrant particular clinical attention, especially when evaluating evidence-based benefits and risks. Because PPIs increase intragastric pH, they can alter the absorption of various medications, leading to possible toxicity or therapeutic failure.[22,33] All PPIs are metabolized by the hepatic CYP450 enzyme system, although each has its own profile that must be considered with regard to being a substrate, inhibitor, or inducer of particular CYP450 isozymes; for example, omeprazole and esomeprazole have been described as inhibiting CYP2C19.[22,33] Further, it remains important to evaluate the relative strength of any inhibitory or inductive CYP450 PPI effects (mild, moderate, strong) to prevent possible toxicity or therapeutic failure.

The potential CYP2C19 interaction with PPIs and clopidogrel (a thienopyridine antiplatelet drug) has generated a substantial amount of interest and debate. In 2009, the FDA issued a labeling change for clopidogrel and a safety warning recommending providers to avoid the coadministration of omeprazole, omeprazole/sodium bicarbonate, or esomeprazole with clopidogrel.[34] In 2010, the American College of Gastroenterology (ACG), American College of Cardiology Foundation (ACCF), and the American Heart Association (AHA) released a consensus statement on the concomitant use of PPIs and thienopyridine antiplatelet drugs. Core recommendations advocate for joint use in patients with a history of upper GI bleeding or in patients at high risk for GI bleeding with multiple risk factors; routine concomitant use of PPIs with thienopyridine antiplatelet drugs is not recommended in patients at low risk for GI bleeding.[35]

Before this 2010 consensus statement, numerous reports suggested an interaction between PPIs and clopidogrel that reduces the antiplatelet effects of clopidogrel and potentially increases the risk of adverse cardiovascular outcomes.[36–40] The hypothesis for this interaction is based on clopidogrel being a prodrug that must undergo biotransformation through CYP2C19 to be converted to its active metabolite. In addition to potential enzyme inhibitory properties, PPIs may be substrates of this enzyme (for their own

metabolism), suggesting a possible competition for the same enzyme binding site as clopidogrel.[37–40] Both hypotheses describe a reduction in the conversion of clopidogrel to its active metabolite and, therefore, a reduction in its efficacy toward platelet inhibition. One important confounding variable involved in the evaluation of this interaction is the role played by genetic polymorphisms in CYP2C19. These can result in loss of functional alleles, which has been related to decreased clopidogrel effectiveness as a result of reduced ability to convert clopidogrel to its active metabolite.[41]

Subsequent ACC/AHA guideline and consensus statements such as the 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction mentions a potential interaction between clopidogrel and omeprazole, but state that the interaction might not be clinically relevant in terms of worsening cardiovascular outcomes.[42] Meta-analyses and systematic reviews are mostly limited to observational data, and have not demonstrated clear or consistent results regarding the clinical relevance of this interaction on cardiovascular outcomes (composite ischemic end points, all-cause mortality, nonfatal myocardial infarctions, stroke, and stent thrombosis).[43–52] One meta-analysis found conflicting results, although aggregate results from randomized controlled trials showed no difference in cardiovascular outcomes.[53] Until more comprehensive evidence becomes available, the most important aspects to consider are to ensure that patients have an appropriate indication for the use of a PPI, to determine that on a case-by-case basis the benefit outweighs the risk, and, if possible, to avoid concomitant use of omeprazole or esomeprazole, PPIs known to be potent inhibitors of CYP2C19, with clopidogrel unless absolutely necessary. Pantoprazole or rabeprazole might be an alternative option given that they have the weakest inhibitory effect on CYP2C19 in the PPI class.[54]

Advancing age, high doses, and longer durations of use (especially for potentially inappropriate indications) have contributed to a growing list of possible side effects and clinical concerns that have unclear causal relationships and mixed, low-quality data.[55,56] The short-term adverse effects of PPIs are relatively infrequent,

tolerable, and comparable to H_2RAs or placebo. The most common side effects include GI discomfort (eg, nausea, diarrhea, abdominal pain), CNS effects (eg, headache, dizziness), and rare isolated reactions (eg, skin rash, increased liver enzymes).[20,57] Long-term PPI use in older patients on high doses has been associated with an increased risk of hip fractures (as well as spine, forearm, and wrist fractures, albeit to a lesser extent).[55,58] The presumed mechanism is inhibition of calcium absorption by PPI-induced hypochlorhydria or through inhibition of proton pumps within the osteoclastic vacuole, resulting in decreased bone resorption.[55,58] A large retrospective cohort study suggested that PPI users had lower baseline bone mineral density than did nonusers, particularly at the femoral neck and total hip, but that PPI therapy was not associated with significant acceleration in bone mineral density loss after 5 and 10 years of follow-up.[59] Although additional research is required to confirm a causal relationship between long-term PPI use and bone fractures, additional bone density testing and calcium supplementation are not suggested beyond age-related recommendations.[59–63]

In addition to fractures, micronutrient deficiencies and infection risk remain among the more pressing and appreciable clinical considerations surrounding long-term PPI use.[55,58] Vitamin B_{12} (cyanocobalamin) deficiency has been described in PPI users, and may occur because gastric acid is required to liberate the vitamin from dietary sources.[55,56,63,64] In a large retrospective case-controlled study, longer duration PPI use (>2 years) as well as higher doses suggested a significant association between either variable and the presence of vitamin B_{12} deficiency.[63] Hypomagnesemia may occur in adults taking PPIs for >1 year, but cases have been reported after 3 months of treatment; the exact mechanism by which PPIs increase the risk of hypomagnesemia is uncertain, but may be associated with altered intestinal absorption of magnesium.[65–67] Malabsorption of iron secondary to long-term gastric acid suppression has been suggested, but has not been confirmed in clinical trials.[55,56] PPIs have also been associated with interstitial nephritis, although an extremely rare finding.[56,68] Pneumonias and enteric infections from

PPIs may stem from the ability of the microorganisms to survive in a less acidic environment.[55,56,60,64,69] Risk considerations and management surrounding PPI use and potential acute nosocomial infections (pneumonia) in critically ill patients is described later (see section on Upper Gastrointestinal Bleeding). The risk of developing community-acquired pneumonia in patients treated with PPIs has also been evaluated in numerous retrospective studies; however, causality has been very difficult to establish and remains controversial.[1,56] Malignancies and enteric (ie, intestinal) infections, most notably *Clostridioides difficile* infection (CDI), have also been described as likely a result of bacterial overgrowth.[1] A retrospective database study of PPI use describes a near-threefold increase in the risk of *C. difficile*–associated diarrhea in patients receiving a PPI versus patients not receiving a PPI.[70] Results from two large meta-analyses suggest that PPI users have upward of a 65% increased risk of developing *C. difficile*–associated diarrhea than do nonusers.[70,71] Although available data may seem compelling, it is mostly observational and of low quality. The true risk seems modest compared to traditional risk factors such as antibiotic use.[1] Because the overall risk of developing CDI remains low, it should not be considered a contraindication to therapy.

Although the long-term adverse effects associated with PPIs are relatively uncommon, the benefit of long-term use must always be weighed against potential risks in each individual patient.

Sucralfate

Sucralfate (an aluminum salt of a sulfated disaccharide) promotes gastric mucosal protection by shielding ulcerated tissue from aggressive factors, such as acid, pepsin, and bile salts.[72] At a pH of 2 to 2.5, sucralfate binds to damaged and ulcerated mucosa, forming a physical barrier against injury from these aggressive factors. The drug has minimal systemic absorption, and does not possess antisecretory activity. It may also have other protective actions related to the stimulation of mucosal prostaglandins.[72] The most

common side effect associated with sucralfate is constipation, which occurs in ~1% to 3% of patients.[72] This is most likely attributable to the aluminum content of the compound, which can also accumulate in patients with renal insufficiency; therefore, long-term use should be avoided.[72] In addition, aluminum salts can bind with dietary phosphate in the GI tract, increasing the potential for hypophosphatemia (see section on Antacids). Sucralfate tablets are large, and some patients, particularly the elderly, may have difficulty swallowing them; a liquid formulation is available for patients with swallowing difficulties. Drug interactions are thought to be caused by binding of the interacting medication with sucralfate in the GI tract, thereby limiting the medication's absorption.[72] Fluoroquinolone antibiotics are most notably associated with this interaction, and concomitant use with sucralfate should be avoided. Single doses of other medications have shown substantial reductions in absorption and bioavailability when given at the same time as sucralfate; often, however, impact on bioavailability was diminished if the interacting drug was given 2 hours before sucralfate.[72] Because of these interactions and findings, sucralfate should be given at least 2 hours after these medications (and avoided altogether with fluoroquinolones). The lack of an antisecretory effect from sucralfate limits its correlation to acid-sensitive drug interactions, as may normally be considered with aluminum-containing antacids.

Misoprostol

Misoprostol is a synthetic prostaglandin E_1 analog that acts primarily by enhancing mucosal defense mechanisms, offering possible value in ulcer management.[73,74] It produces cytoprotective effects by stimulating the production of mucus and bicarbonate, improving mucosal blood flow, and reducing mucosal cell turnover similar to the effects of endogenous prostaglandin.[73] Misoprostol also produces a dose-dependent inhibition of gastric acid, but even at high doses, the inhibition is less than that of H_2RAs. The use of misoprostol is limited because of its potential to cause dose-dependent diarrhea (in up to

30% of patients) and abdominal cramping.[73] Taking the drug with meals may help reduce the incidence of diarrhea. Decreasing the daily dose may also reduce diarrhea, but efficacy may be compromised.[74] Other troublesome side effects include nausea, flatulence, and headaches. Misoprostol is an abortifacient because of its uterotropic effects that also may be used for cervical ripening during labor induction. It is contraindicated in pregnant females; use in females of child-bearing age requires a negative serum pregnancy test result and adequate contraception.[73,74]

Bismuth Salts

Bismuth subsalicylate has been used for years as an OTC option for many GI ailments. Although its mechanism of action is not completely understood, it is thought to work by binding to and protecting mucosal lesions and enhancing cellular protective mechanisms. Bismuth lacks acid-inhibitory effects, but has an antimicrobial effect, primarily against *H. pylori*, and is available as both subsalicylate and subcitrate salts.[75] These salts have few side effects, but may have reduced elimination in patients with renal impairment. They are associated with a harmless black coloring of the stools because of colonic conversion of bismuth to bismuth sulfide and a potential black discoloration of the tongue with liquid dosage forms.[5] Bismuth subsalicylate should be used with caution in patients on concomitant salicylates because of the potential for salicylate toxicity or increased bleeding risk; it is generally not recommended for children and patients with salicylate allergies or sensitivities, and long-term use is not advised.[5] At the time of this writing, bismuth subcitrate is only available in the United States by prescription in a combination product with metronidazole and tetracycline for the treatment of *H. pylori* infection; it lacks salicylate, but otherwise presents benefits and risks similar to that of bismuth subsalicylate.[76]

DYSPEPSIA

Dyspepsia refers to a subjective feeling of pain or discomfort located primarily in the upper abdomen. It is a common problem that affects about 25% of the U.S. population accompanied by substantial costs to the health care system.[77–79] The etiology of dyspepsia in ~25% of patients seems to be secondary to an organic disease, such as PUD, GERD with or without esophagitis, or gastric malignancy (uncommon in North America), or otherwise drug-induced disease from medications such as nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics such as erythromycin and tetracycline, iron and potassium supplements, digoxin, theophylline, and bisphosphonates.[80,81] Smoking or a stressful lifestyle can also play a role in dyspepsia (**Fig. 23-3**). The other 75% of patients are defined to have functional dyspepsia (idiopathic) who have undergone diagnostic evaluation (usually upper endoscopy) to rule out any organic pathology.[80] Heartburn may coexist with dyspepsia, but is usually suggestive of GERD.

(Longstreth GF, Lacy BE. Approach to the adult with dyspepsia. *UpToDate*. UpToDate; 2020. Accessed November 8, 2020. www.uptodate.com)

Functional dyspepsia, also known as idiopathic or nonulcer dyspepsia (NUD), is a clinical syndrome in which there is no evidence of mucosal damage related to PUD, GERD, or malignancy found at endoscopy. Functional dyspepsia is defined based on the Rome IV diagnostic criteria.[81–83] It includes the presence of one or more of the following for the past 3 months, with symptom onset 6 months before diagnosis, and without evidence of structural anatomic symptoms.[84,85]

- Postprandial fullness (classified as postprandial distress syndrome)
- Early satiation (inability to finish a normal-sized meal, also classified as postprandial distress syndrome)
- Epigastric pain or burning (classified as epigastric pain syndrome)

It should be noted that any of these criteria can overlap.[82] A cross-sectional population-based study performed in the United States, United Kingdom, and Canada found that about 10% of the adult population meets Rome IV criteria to be diagnosed with functional dyspepsia.[83]

Pathophysiology

Acute, infrequent dyspepsia is most often related to food, alcohol, smoking, or stress. Chronic dyspepsia may be related to an underlying cause, such as PUD, GERD, or malignancy, or may not have any known cause (endoscopy-negative, functional, idiopathic dyspepsia). Functional dyspepsia may involve delayed gastric emptying; there is also evidence that the esophagus, stomach, duodenum, and other regions of the GI tract are hypersensitive, and may be associated with irritable bowel syndrome, especially in females.[85] However, a pathologic association between functional dyspepsia and gastroduodenal motility, hypersensitivity, or any other GI abnormality remains to be more clearly elucidated because psychological disturbances seem to also be an important contributing factor. Although *H. pylori* infection has been identified in 20% to 60% of patients with functional dyspepsia, its pathophysiologic relevance remains uncertain.[84]

Clinical Assessment and Diagnosis

Acute, infrequent dyspepsia is usually self-limiting and generally requires no further investigation. Chronic dyspeptic symptoms cannot be used to predict endoscopic findings of PUD, GERD, or malignancy in patients with uninvestigated dyspepsia.[85–87] In addition, individual symptoms or symptom subgroups, such as PUD-like, GERD-like, or dysmotility-like dyspepsia, are not useful in distinguishing organic disease from functional dyspepsia, nor do they aid in management. This is because there is considerable overlap of symptoms among patients with PUD, GERD, malignancy, and functional dyspepsia.

The clinical assessment of uninvestigated dyspepsia in patients younger than 60 years of age with no alarm signs or symptoms includes a test-and-treat *H. pylori* option (**Fig. 23-3**).[81] Testing for *H. pylori* should be conducted using a nonendoscopic-validated test (see section on Tests for Detecting *Helicobacter pylori*). New-onset dyspepsia in an older individual is considered an independent risk

factor for an underlying malignancy such as gastric cancer.[85] As such, all patients ages 60 years and older with dyspepsia should undergo upper endoscopy (**Fig. 23-3**).[81] Guidelines do not recommend endoscopy in patients younger than age 60 unless they present with clinically significant weight loss (>5% body weight over the past 6–12 months), overt GI bleeding, or multiple or rapidly progressive alarm symptoms (**Fig. 23-3**).[81] It should be noted that the age threshold was increased from 55 to 60 years based on economic analyses showing only borderline cost-effectiveness of endoscopy at age 55.[88] Owing to seemingly limited value in using alarm symptoms to pursue upper endoscopy, it should not solely be used to rule out malignancy.[81,89] Other alarm features that assist in identifying serious underlying disease, especially malignancy, include early satiety, anorexia, worsening dysphagia or odynophagia, unexplained weight loss (>10% body weight), vomiting, anemia, GI bleeding, lymphadenopathy, jaundice, a history of PUD, a family history of upper GI tract cancer, previous gastric surgery, or other malignancy.[85]

Treatment

The recommended strategies for managing dyspepsia in adults are presented in **Figure 23-3**. Individuals with acute dyspepsia can be effectively treated with self-directed therapy using antacids or OTC antisecretory drugs if they are unable or unwilling to avoid offending foods and beverages, stop smoking, or discontinue offending medications. The initial management of patients younger than 60 years of age with uninvestigated chronic dyspepsia and no alarm features depends on the presence or absence of *H. pylori* (**Table 23-2**; **Fig. 23-3**).[81] Empiric therapy with the lowest PPI dose is considered first line if patients are *H. Pylori* negative or otherwise remain symptomatic after *H. Pylori* eradication therapy.[81] Studies have not shown a significant difference in using once-daily versus twice-daily PPI therapy for dyspepsia; as such, the lowest dose should be trialed first and titrated to symptom improvement.[85–87,90]

PPIs should be discontinued after 1 month if the patient's symptoms respond to treatment. H_2RAs are an appropriate substitute to PPIs in patients with dyspepsia because randomized controlled trials found no statistically significant difference between them with regard to providing symptom relief.[81] However, patients who are *H. pylori* positive should receive treatment for eradication (see section on *Helicobacter pylori*–Related Ulcers).[84–87]

Table 23-2
Indications for Testing and Treating *Helicobacter pylori* Infection

Recommended (Evidence Established)
Uninvestigated dyspepsia (depending on *H. pylori* prevalence)
PUD (active gastric or duodenal ulcer)
History of PUD (confirmed ulcer not previously treated for *H. pylori*)
Gastric MALT lymphoma
After resection of early gastric cancer
Reduce the risk of recurrent bleeding from gastroduodenal ulcer
Controversial (Evidence Not Well Established)
NUD
Individuals using NSAIDs (no signs/symptoms of peptic ulcer)
GERD
Individuals at risk for gastric cancer
Individuals with unexplained iron deficiency anemia

GERD, gastroesophageal reflux disease; MALT, mucosa-associated lymphoid tissue; NSAID, nonsteroidal anti-inflammatory drug; NUD, nonulcer dyspepsia; PUD, peptic ulcer disease.

Early endoscopy with biopsy for *H. pylori* is recommended for all patients 60 years of age or older with uninvestigated chronic dyspepsia; it is also recommended for those younger than 60 years of age, but only if they present with the aforementioned symptoms (**Fig. 23-3**).[81] In the event that an abnormality (such as PUD, GERD,

or malignancy) is found, it should be treated accordingly. If no abnormality is identified, the treatment algorithm for those younger than age 60 years who are otherwise not candidates for endoscopy should be utilized (**Fig. 23-3**).[81] The medical management of functional dyspepsia (eg, NUD) is challenging and, when possible, should take into consideration the cost-effectiveness of treatment.[85–87] Although pharmacotherapy is considered for most patients, evidence of benefit is limited because of the lack of well-designed studies and an incomplete understanding of the disorder. Meta-analyses have demonstrated the efficacy of H_2RAs and PPIs, but there is no evidence to support the use of antacids, sucralfate, and misoprostol.[91,92] Antidepressants, particularly tricyclic antidepressants, are often recommended for patients with functional dyspepsia. Although they may have some benefit, the mechanism for this finding is unclear, and published clinical trials are small and of poor quality, resulting in uncertain efficacy.[85,87,91] Although benefit from prokinetic agents has been reported, most studies were conducted with cisapride, which was withdrawn from the U.S. market.[91] The use of available prokinetic agents (eg, metoclopramide) should be reserved for difficult-to-treat patients or those with gastroparesis because of side effects and relatively limited efficacy; they should also not be used for >12 weeks.[85,87] Guidelines recommend against the combination of prokinetic agents and H_2RAs in functional dyspepsia because the combination was not shown to be more effective than using either agent alone.[81] Alternative therapies, including herbal products, remain unproved.[85] Patients with persistent dyspepsia despite a negative endoscopy finding, in whom PPI therapy and *H. pylori* eradication fails, should have their diagnosis reevaluated.

PEPTIC ULCER DISEASE

PUD is one of the most common diseases affecting the upper GI tract.[93] Chronic peptic ulcers are defects in the gastric (gastric ulcer) or duodenal (duodenal ulcer) mucosa that require gastric acid for their formation. Chronic peptic ulcers differ from erosions and gastritis in that the ulcer extends deeper into the muscularis mucosa.[93,94]

Stress ulcer is an acute form of peptic ulcer, but it occurs primarily in critically ill patients and differs in its underlying pathogenesis (see section on Stress-Related Mucosal Bleeding).

Epidemiology

It is difficult to estimate the epidemiology of PUD because of the different methods used to diagnose peptic ulcers (eg, symptom-based, ulcer-related complications, radiology, or endoscopy) along with differences in NSAID use, *H. pylori* prevalence, and cigarette smoking. Improved medical treatment, changes in the criteria and coding for hospitalizations and mortality, and the evolution from hospital-based to ambulatory care have also altered the epidemiology of PUD.[93] Current data suggest a shift in the prevalence of PUD in the United States from predominantly males to a comparable rate in males and females.[93] A declining ulcer rate in younger individuals and an increasing rate for older adults reflect a decline in *H. pylori* infection and an increased use of NSAIDs in the United States. Office visits, hospitalizations, and deaths have modestly declined during the past four decades, but deaths among older patients (older than 75 years) have increased and are most likely related to NSAID use.[93]

Etiology and Risk Factors

H. pylori and NSAIDs are the two most common causes of chronic PUD, and influence the chronicity of the disease.[93] Less common causes include hypersecretory states, such as ZES (see section on Zollinger–Ellison Syndrome), viral infections (eg, cytomegalovirus),

radiation, and chemotherapy (eg, hepatic artery infusion). Factors that may increase the risk of a peptic ulcer include alcohol ingestion, cigarette smoking, psychological stress, corticosteroid use, organ transplantation, and certain conditions such as renal failure, cirrhosis, pancreatitis, obstructive pulmonary disease, or Crohn disease.[93]

HELICOBACTER PYLORI–RELATED ULCERS

H. pylori infection is causally linked to chronic gastritis, PUD, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer (**Table 23-2**).[93–98] The lifetime risk of exhibiting an endoscopic ulcer in *H. pylori*–positive individuals is 10% to 20%.[93,94] Worldwide, infected individuals have a two- to sixfold increased risk of developing gastric cancer and MALT lymphoma when compared to noninfected individuals.[99] Differences in strains and host-specific factors account for the variable pathogenesis of the organism.[94,97] There is increasing evidence that iron deficiency anemia and idiopathic thrombocytopenia are associated with *H. pylori* infection, but cause and effect remain unproved.[95,100] The association between *H. pylori* and PUD bleeding remains unclear, but *H. pylori* eradication decreases recurrent bleeding (see section on Upper Gastrointestinal Bleeding).[95]

Table 23-3
Risk Factors for Nonsteroidal Anti-inflammatory Drug–Induced Ulcer and Ulcer-Related Upper Gastrointestinal Complications

Established
Confirmed prior ulcer or ulcer-related complication Age >65 years Multiple or high-dose NSAID use Concomitant use of aspirin (including low cardioprotective dosages, eg, 81 mg) Concomitant use of an anticoagulant, corticosteroid, bisphosphonate, clopidogrel, or SSRI Selection of NSAID (selectivity of COX-1 vs COX-2)
Controversial

Established
Helicobacter pylori Alcohol consumption Cigarette smoking

COX-1, cyclooxygenase-1; COX-2, cyclooxygenase-2; NSAID, nonsteroidal anti-inflammatory drug; SSRI, selective serotonin reuptake inhibitor.

The prevalence of *H. pylori* varies by geographic location, socioeconomic status, ethnicity, and age, and is more common in developing countries than in industrialized nations.[94] The overall prevalence in the United States is estimated to be 30% to 40%, but is higher in older individuals (50%–60%) than in children (10%–15%).[94] In general, rates are lower in those born in North America than in other parts of the world.[99]

Transmission occurs usually during childhood from the infected person by either the gastro-oral (vomitus) or fecal–oral (diarrhea) route, or from fecal-contaminated water or food.[94,96] Individuals living in the same household with an *H. pylori*–positive person, especially

when there is household crowding, are at increased risk for acquiring the infection.[94,96]

Nonsteroidal Anti-inflammatory Drug–Induced Ulcers

There is considerable evidence linking the chronic use of NSAIDs with GI injury.[93,101–104] Endoscopically confirmed gastric and duodenal ulcers develop in 15% to 30% of chronic NSAID users, 2% to 4% of whom experience ulcer-related bleeding or perforation.[101,102] Gastric ulcer is most common, and develops primarily in the antrum. NSAIDs may also cause ulcers in the esophagus and the colon, but these ulcers occur less frequently and differ in their underlying pathogenesis.[101,104] It is estimated that NSAIDs account for ~100,000 hospitalizations and 7000 to 10,000 deaths annually in the United States, although mortality may be overstated because of a recent decline in hospitalizations.[102] A national prescription audit in the United States revealed an annual NSAID cost of $4.9 billion, with additional nonprescription NSAID sales of $3 billion.[105,106] Risk factors for NSAID-induced ulcers and upper GI complications are listed in **Table 23-3**. Combinations of factors confer an additive risk.

Pathophysiology

A physiologic balance exists in healthy individuals between gastric acid secretion and gastroduodenal mucosal defense. Peptic ulcers occur when the balance between aggressive factors (gastric acid, pepsin, bile salts, *H. pylori*, and NSAIDs) and mucosal defensive mechanisms (mucosal blood flow, mucus, mucosal bicarbonate secretion, mucosal cell restitution, and epithelial cell renewal) are disrupted.[93,103] Increased acid secretion may occur in patients with duodenal ulcer, but most patients with gastric ulcer have normal or reduced rates of acid secretion.[3] Pepsin is an important cofactor that plays a role in the proteolytic activity involved in ulcer formation. Mucosal defense and repair mechanisms protect the gastroduodenal

mucosa from noxious endogenous and exogenous substances.[93] The viscous nature and near-neutral pH of the mucus–bicarbonate barrier protect the stomach from the acidic contents in the gastric lumen. The maintenance of mucosal integrity and repair are mediated by the production of endogenous prostaglandins. When aggressive factors alter mucosal defense mechanisms, back diffusion of hydrogen ions occurs with subsequent mucosal injury. *H. pylori* and NSAIDs cause alterations in mucosal defense by different mechanisms, and are important factors in the formation of peptic ulcers.

HELICOBACTER PYLORI–RELATED ULCERS

H. pylori is a gram-negative, spiral-shaped bacillus that thrives in a microaerophilic environment. The bacterium resides between the mucous layer and surface epithelial cells in the stomach or in any location where gastric-type epithelium is found.[94] Flagella enable it to move from the lumen of the stomach, where the pH is low, to the mucous layer, where the pH is neutral. Acute infection is accompanied by transient hypochlorhydria, which enables the organism to survive the acidic gastric juice. Although the exact method by which *H. pylori* induces hypochlorhydria is uncertain, it is hypothesized that its urease-producing ability hydrolyzes urea in the gastric juice and converts it to ammonia and carbon dioxide, which creates a neutral microenvironment that surrounds the bacterium.[94,103] Adherence pedestals attach to gastric-type epithelium and prevent the bacterium from being shed during cell turnover and mucous secretion.

Disease outcome depends on the patterns of *H. pylori* colonization and inflammation within the stomach.[94,103] Colonization of the antrum and acid-secreting body of the stomach (corpus) is associated with gastric ulcer and gastric adenocarcinoma, and is typically accompanied by gastric atrophy and decreased acid secretion. When *H. pylori* colonizes, the antrum and the body of the stomach are spared, the risk of duodenal ulcer is increased, and gastric acid is normal or slightly increased. Ulcers in the duodenum arise from

the colonization by antral organisms of gastric-type epithelium that develops in the duodenum in response to changes in duodenal pH.[94] Direct mucosal damage is produced by virulence factors (eg, cytotoxin-associated gene, vacuolating cytotoxin), elaborating bacterial enzymes (eg, urease, lipases, proteases), and adherence.[94,103,107] *H. pylori* infection may also cause alterations in the host immune response.[94,107] Host polymorphisms related to interleukin (IL)-1β and its receptor antagonist, tumor necrosis factor α (TNF-α), and IL-10, may be associated with increased gastric acid secretion and duodenal ulcer or acid suppression and gastric cancer.[94,107]

Nonsteroidal Anti-inflammatory Drug–Induced Ulcers

Nonselective NSAIDs (**Table 23-4**), including aspirin, cause peptic ulcers and upper GI complications by systemically inhibiting protective prostaglandins in the gastric mucosa.[93,101,103] NSAIDs inhibit cyclooxygenase (COX), the rate-limiting enzyme in the conversion of arachidonic acid to prostaglandins. There are two COX isoforms: COX-1, which is found in the stomach, kidney, intestine, and platelets; and COX-2, which is induced with acute inflammation.[93,101] The inhibition of COX-1 is associated with upper GI (including ulcers) and renal toxicity, and the inhibition of COX-2 is related to anti-inflammatory effects.[93,101] Nonselective NSAIDs, including aspirin, inhibit both COX-1 and COX-2 to varying degrees and decrease platelet aggregation, which may increase the risk of upper GI bleeding.[93,101] The coadministration of selected NSAIDs (eg, ibuprofen) with aspirin also reduces the antiplatelet effects of aspirin.[108] Although prostaglandin inhibition is regarded as the major cause of gastric ulcers, diversion of arachidonate through the lipoxygenase pathway enhances leukotriene synthesis and results in vasoconstriction and release of oxygen free radicals, which may also contribute to impairment of mucosal defense.[101] Further, there is increasing evidence that NSAIDs may cause gastric damage by

interfering with the mucosal synthesis of nitric oxide and hydrogen sulfide, important mediators in maintaining gastric mucosal integrity.[101]

Table 23-4
Selected Nonsteroidal Anti-inflammatory Drugs

Salicylates
Acetylated: aspirin
Nonacetylated: trisalicylate, salsalate
Nonsalicylates[a]
Nonselective (traditional) NSAIDs: ibuprofen, naproxen, tolmetin, fenoprofen, sulindac, indomethacin, ketoprofen, ketorolac, flurbiprofen, piroxicam
Partially selective NSAIDs: etodolac, diclofenac, meloxicam, nabumetone
Selective COX-2 inhibitors: celecoxib[b], rofecoxib[c], valdecoxib[c]

COX-2, cyclooxygenase-2; NSAID, nonsteroidal anti-inflammatory drug.

[a]Based on COX-1/COX-2 selectivity ratio in vitro.

[b]Initially marketed as a COX-2 inhibitor, but current U.S. Food and Drug Administration (FDA) labeling is consistent with nonselective and partially selective NSAIDs.

[c]Withdrawn from the U.S. market.

The relative COX selectivity among NSAIDs varies, and is thought to be an important factor in determining the propensity for ulcer formation.[93,101] Partially selective NSAIDs that inhibit COX-2 more than COX-1 (**Table 23-4**) may be associated with less GI toxicity, but there are few controlled trials to support this claim.[93,101,109,110] The selective COX-2 inhibitors rofecoxib and valdecoxib do not inhibit gastric mucosal prostaglandin synthesis or serum thromboxane A_2, which accounts for their improved GI safety; however, they were withdrawn from the U.S. market in 2004 because of concerns about cardiovascular safety.[93,101,110] Celecoxib, an NSAID originally marketed as a selective COX-2 inhibitor, currently remains available in the United States despite similar concerns about cardiovascular risk, especially at higher doses.[93] However, the risk of gastric ulcer

and upper GI complications with celecoxib seems lower than that with rofecoxib and valdecoxib, suggesting it may not be as selective for COX-2 as originally hypothesized.[93]

Aspirin and nonaspirin NSAIDs also have a topical (direct) irritating effect on the gastric mucosa, but the resulting inflammation and erosions usually heal within a few days. Gastric damage is associated with the acidic properties of aspirin and nonaspirin NSAIDs and their ability to decrease the hydrophobicity of the mucous gel layer in the gastric mucosa.[101,111] Thus, direct mucosal injury appears to correlate with the pK_a of a compound—suggesting the lower the acidity of the drug, the less the short-term topical damage.[101] Formulations, such as enteric-coated aspirin, buffered aspirin, NSAID prodrugs, and parenteral or rectal preparations, may spare topical effects on the gastric mucosa, but all have the potential to cause a gastric ulcer because of their systemic inhibition of endogenous prostaglandins.[93,112]

Clinical Presentation

SIGNS AND SYMPTOMS

The signs and symptoms associated with a peptic ulcer range from mild epigastric pain to life-threatening upper GI complications.[93,103] A change in the character of the pain may indicate an ulcer-related complication. The absence of epigastric pain, especially in older adults who are taking NSAIDs, does not exclude the presence of an ulcer or related complications. Although the reasons for this are unclear, they may be related to the analgesic effect of the NSAID. There is no one sign or symptom that differentiates an *H. pylori*–related ulcer from an NSAID-induced ulcer. Ulcer-like symptoms may occur in the absence of peptic ulceration in association with *H. pylori*–related gastritis or duodenitis.

COMPLICATIONS

The most serious life-threatening complications associated with chronic PUD are upper GI bleeding, perforation into the abdominal

cavity or penetration into an adjacent structure (eg, pancreas, liver, or biliary tract), and obstruction.[93,103,113] Ulcer-related bleeding is the most frequent complication and occurs with all types of ulcers (see section on Upper Gastrointestinal Bleeding). The incidence of ulcer-related upper GI bleeding and perforation is highest in individuals taking NSAIDs who are older than age 60 years.[101,103] The bleeding may be occult (hidden) or present as melena (black-colored stools) or hematemesis (vomiting of blood). Mortality is higher in patients who continue to bleed or who rebleed after the initial bleeding has stopped and in patients with a perforated ulcer.[2,114] The pain associated with perforation is typically sudden, sharp, and severe, beginning in the epigastric area but quickly spreading throughout the upper abdominal area. Gastric outlet obstruction, the least frequent complication, is caused by previous ulcer healing and scarring or edema of the pylorus or duodenal bulb and can lead to symptoms of gastric retention, including early satiety, bloating, anorexia, nausea, vomiting, and weight loss.

Clinical Assessment and Diagnosis

TESTS FOR DETECTING HELICOBACTER PYLORI

The detection of *H. pylori* infection can be made through gastric mucosal biopsies in patients undergoing upper endoscopy or by nonendoscopic tests (**Table 23-5**).[94,95,115] Any patient who tests positive for *H. pylori* should be offered treatment. Patients indicated for testing include any individual with active or previous confirmed history of PUD (not previously treated for *H. pylori*), history of low-grade gastric MALT lymphoma, or a history of endoscopic resection of early gastric cancer. Recent guidelines also recommend that clinicians consider testing in individuals starting on long-term NSAID therapy, those with unexplained iron deficiency anemia, and adults with idiopathic thrombocytopenic purpura.[95] The selection of a specific method is influenced by the clinical circumstance and the availability and cost of the individual test. Endoscopic tests require a mucosal biopsy for the rapid urease test, histology, or bacterial

culture (which is less common). Medications that reduce urease activity or the density of *H. pylori* may decrease the sensitivity of the rapid urease test by up to 25%.[95] For this reason, when possible, antibiotics and bismuth salts should be withheld for 4 weeks, whereas H_2RAs and PPIs should be withheld for 1 to 2 weeks before endoscopic testing. Patients who are taking these medications at endoscopy will require histology in addition to the rapid urease test. At least three biopsies are taken from different areas of the stomach because patchy distribution of *H. pylori* can result in false-negative results. Acute ulcer bleeding at the time of testing is likely to decrease the sensitivity of the rapid urease test and histology and increase the likelihood of false-negative results.[95,116]

Table 23-5

Diagnostic Tests for *Helicobacter pylori* Infection

Tests Using Gastric Mucosal Biopsy in Patients Undergoing Endoscopy
Rapid Urease Test
Tests for active *H. pylori* infection; >90% sensitivity and specificity In the presence of *H. pylori* urease, urea is metabolized to ammonia and bicarbonate resulting in an increase in pH, which changes the color of a pH-sensitive indicator. Results are rapid (within 24 hours), and test is less expensive than is histology or culture. Withhold H_2RAs and PPIs 1–2 weeks before testing and antibiotics and bismuth salts 4 weeks before testing to reduce the risk of false negatives.
Histology
"Gold standard" for detection of active *H. pylori* infection and associated lesions; >95% sensitive and specific Permits further histologic analysis and evaluation of infected tissue (eg, gastritis, ulceration, adenocarcinoma); tests for active *H. pylori* infection Results are not immediate; not recommended for initial diagnosis; more expensive than is rapid urease test.
Culture
Permits sensitivity testing to determine antibiotic choice or resistance; tests for active *H. pylori* infection. High specificity, but low sensitivity due to difficulty culturing *H. pylori* Use usually limited to patients who fail initial course of eradication therapy

Tests Using Gastric Mucosal Biopsy in Patients Undergoing Endoscopy

Nonendoscopic Tests That Do Not Use Gastric Mucosal Biopsy

Urea Breath Test

Tests for active *H. pylori* infection; >95% sensitive and specific

Radiolabeled urea with either ^{13}C or ^{14}C is given orally; urease secreted by *H. pylori* in the stomach (if present) hydrolyzes radiolabeled urea to produce radiolabeled CO_2, which is exhaled and then quantified from the expired breath; radiation exposure is minimal.

Withhold H_2RAs and PPIs 1–2 weeks before testing and antibiotics and bismuth salts 4 weeks before testing to reduce the risk of false negatives.

Used to detect *H. pylori* before treatment and to document posttreatment eradication

Results usually take about 2 days; less expensive than are tests that utilize gastric mucosal biopsy, but more expensive than serologic tests; availability and reimbursement is inconsistent.

Antibody Detection (In-Office or Near Patient)

Qualitative test; detects IgG antibodies to *H. pylori* in whole blood or finger stick.

Effective for primary diagnosis, but not of benefit in confirming eradication because antibodies to *H. pylori* remain positive for years after successful eradication of the infection.

Results obtained quickly (usually within 15 minutes) but reduced sensitivity and specificity compared with laboratory-based tests; widely available and inexpensive.

Results not affected by H_2RAs, PPIs, or bismuth; antibiotics given for other indications may result in a positive antibody test.

Antibody Detection (Laboratory)

Quantitative test; detects IgG antibodies to *H. pylori* in serum using laboratory-based ELISA tests and latex agglutination techniques.

More accurate than in-office tests; similar sensitivity and specificity to rapid urease biopsy and urea breath tests.

Unable to determine whether antibody is related to active or cured infection; antibody titers vary between individuals and take up to 6 months to 1 year to return to the uninfected state.

Results not affected by H_2RAs, PPIs, or bismuth; antibiotics given for other indications may result in a positive antibody test.

Fecal Antigen Test

Tests Using Gastric Mucosal Biopsy in Patients Undergoing Endoscopy
An enzymatic immunoassay test that identifies *H. pylori* antigen in stool; sensitivity and specificity comparable to the UBT for initial diagnosis
H_2RAs, PPIs, antibiotics, and bismuth may cause false-negative results, but to a lesser extent than is the UBT.
Considered an alternative to detecting *H. pylori* before treatment and documenting posttreatment eradication; patients may have a reluctance to obtain stool samples.

ELISA, enzyme-linked immunosorbent assay; H_2RA, H_2 receptor antagonist; IgG, immunoglobulin G; PPI, proton-pump inhibitor; UBT, urea breath test.

Wiley-Blackwell; 2009:1005; Chey WD, Wong BCY, Practice Parameters Committee of the American College of Gastroenterology. American College of Gastroenterology guideline on the management of *Helicobacter pylori* infection. *Am J Gastroenterol*. 2007;102:1808–1825; Calvet X, Lehours P, Lario S, Mégraud F. Diagnosis of *Helicobacter pylori* infection. *Helicobacter*. 2010;15(suppl 1):7–13; Francis M, Lehours P. *Helicobacter pylori* detection and antimicrobial susceptibility testing. *Clin Microbiol Rev*. 2007;20(2):280–322.

Nonendoscopic tests include the urea breath test (UBT), stool antigen, or serology to identify active infection or detect antibodies to *H. pylori.*[94,95,115] The UBT, the most accurate noninvasive test, detects active *H. pylori* infection and is also effective after eradication treatment.[94,95,115] The ^{13}C (nonradioactive isotope) and ^{14}C (radioactive isotope) tests require that the patient ingest radiolabeled urea, which is then hydrolyzed by *H. pylori* (if present in the stomach) to ammonia and radiolabeled bicarbonate. The radiolabeled bicarbonate is absorbed in the blood and detected in expired breath. The in-office and laboratory antibody tests are a cost-effective method to initially diagnose *H. pylori* infection, but because they do not differentiate between active infection and previously eradicated *H. pylori*, they should not be used to confirm eradication.[94,95,115] The fecal antigen test identifies *H. pylori* antigens in the stool, and is less expensive and easier to perform than is the UBT.[94,95,115] Although usually comparable with the UBT in the initial detection of *H. pylori,* the fecal antigen test may be less accurate when used to document eradication posttreatment.

LABORATORY TESTS, RADIOGRAPHY, AND ENDOSCOPY

Generally, laboratory tests are not helpful in the diagnosis of PUD. Fasting serum gastrin concentrations are only recommended for patients who are unresponsive to therapy or those suspected of having a hypersecretory disease. Serum hematocrit (Hct) and hemoglobin (Hgb), as well as guaiac fecal occult blood tests, assist in the evaluation of ulcer-related bleeding.

Gastric acid–secretory studies are not routinely performed in patients suspected of having an uncomplicated peptic ulcer. However, measurements of acid secretion are instrumental in the evaluation of patients with severe, recurrent PUD that is unresponsive to standard drug therapy. Acid secretion is expressed as basal acid output (BAO), in response to a meal (meal-stimulated acid secretion), or as maximal acid output (MAO).[3] These tests estimate the acid-secretory response under various circumstances, and are measured by inserting a nasogastric tube into the stomach and aspirating the gastric contents.[3] The aspirate is estimated by titration with a basic solution of known concentration and expressed as milliequivalents of H^+ per hour. Results obtained for an individual patient are then compared with standard ranges for each test. The BAO, meal-stimulated acid secretion, and MAO vary according to age, sex, health, and time of day. The BAO follows a circadian rhythm, with the highest acid secretion occurring at night and the lowest in the morning. An increase in the BAO/MAO ratio suggests a basal hypersecretory state such as ZES.

Confirmation of a peptic ulcer requires visualizing the ulcer by either GI radiography or upper endoscopy.[93] Radiography is sometimes the initial diagnostic procedure because it is less expensive than is endoscopy and more widely available, although small ulcers are often difficult to detect and false positives may result from trapped barium.[93] Fiberoptic upper endoscopy (esophagogastroduodenoscopy [EGD]) is the gold standard because it detects >90% of peptic ulcers and permits direct inspection, biopsy, and visualization of superficial erosions and sites of active bleeding. Upper endoscopy is preferred if complications are suspected or if an

accurate diagnosis is required. If a gastric ulcer is found on radiography, malignancy should be excluded by direct endoscopic visualization and histology.

Clinical Course and Prognosis

The natural history of PUD is characterized by periods of exacerbations and remissions unless the underlying cause is removed.[93] *H. pylori* and NSAIDs are the two most important risk factors for the development of peptic ulcer.[93] Successful eradication of *H. pylori* heals ulcers and dramatically decreases ulcer recurrence and GI complications.[93] The risk of NSAID-induced ulcer and life-threatening GI complications is greatest in the elderly and those with a history of PUD. Prophylactic co-therapy and/or the use of a more COX-2–selective inhibitor markedly decreases ulcer risk and complications.[101,102] Gastric cancer in *H. pylori*–infected individuals develops slowly over 20 to 40 years, and is associated with a slightly higher lifetime risk when compared with that in patients with duodenal ulcer or in the general population.[94,97,98]

Treatment

THERAPEUTIC GOALS

The therapeutic goals for treating PUD in adults depend on whether the ulcer is related to *H. pylori* or associated with an NSAID. Treatment goals may differ depending on whether the ulcer is initial or recurrent and whether complications have occurred. Treatment is aimed at relieving ulcer symptoms, healing the ulcer, preventing ulcer recurrence, and reducing ulcer-related complications. When possible, the most cost-effective drug regimen should be utilized.

NONPHARMACOLOGIC THERAPY

Patients with PUD should discontinue NSAIDs (including aspirin) if possible. Patients unable to tolerate certain foods and beverages (eg, spicy foods, caffeine, and alcohol) may benefit from dietary

modifications. Lifestyle modifications such as stress reduction and decreasing or stopping tobacco use should be encouraged. Probiotics, particularly strains of lactic acid–producing bacteria such as *Lactobacillus* and *Bifidobacterium,* lactoferrin, and certain foods (eg, cranberry juice, ginger, chili, oregano, some milk proteins) have been used as adjuvant *H. pylori* therapy.[93,117–119] Probiotics can help reduce the side effects of the antibiotics used for eradication; however, most studies related to probiotic effectiveness in cure rates were performed in China with no optimal dose, timing, or duration of therapy that could be established. Current guidelines indicate that more research is needed before widespread recommendations can be made.[120,121] Patients with ulcer-related complications may require surgery for bleeding, perforation, or obstruction.[93] Surgery for medical treatment failures (eg, vagotomy with pyloroplasty or vagotomy with antrectomy) is rarely performed because of effective medical management and the risk of postoperative complications from surgery.

PHARMACOTHERAPY

Drug regimens used to eradicate *H. pylori* are identified in **Table 23-6**. As previously noted, all patients with a positive *H. pylori* test finding should be offered treatment.[95] Recommended first-line treatment in the United States includes a clarithromycin-based three-drug regimen (standard triple therapy) for 14 days or a bismuth-based four-drug regimen (standard quadruple therapy) for 10 to 14 days (**Fig. 23-4**). Treatment selection should be based on a patient's previous antibiotic exposure and current resistance rates. Another treatment option is sequential therapy; however, its effectiveness has not been validated in North America.[95] If initial eradication fails, a second course of therapy (ie, salvage therapy) should be offered based on the selection of antibiotics that have not been previously used. Successful treatment eradicates the infection and heals the ulcer. Treatment of *H. pylori*–positive patients with a conventional antiulcer drug or combining an antisecretory drug with sucralfate is not recommended because of high rates of ulcer recurrence and

complications. Maintenance therapy with a PPI or H_2RA (Table 23-1) should only be necessary in high-risk patients with a history of ulcer complications, those with *H. pylori*–negative ulcers, and patients with other concomitant acid-related diseases (eg, GERD).

Table 23-6
Oral Drug Regimens Used to Eradicate *Helicobacter pylori* Infection

Drug Regimen	Dose	Frequency	Duration
Clarithromycin-Based Three-Drug Regimens			
PPI	Standard dose[a]	bid[a]	14 days[b]
Clarithromycin	500 mg	bid	14 days[b]
Amoxicillin[c]	1 g	bid	14 days[b]
Or			
PPI	Standard dose[a]	bid[a]	14 days[b]
Clarithromycin	500 mg	bid	14 days[b]
Metronidazole[c]	500 mg	bid	14 days[b]
Bismuth-Based Four-Drug Regimens			
Bismuth subsalicylate[d]	525 mg	qid	10–14 days
Metronidazole[c]	250–500 mg	qid	10–14 days
Tetracycline plus	500 mg	qid	10–14 days
PPI	Standard dose[a]	Daily or bid[a]	10–14 days
Or			
H_2RA[e]	Standard dose[e]	bid[e]	4–6 weeks
Sequential Therapy[f]			
PPI	Standard dose[a]	bid[a]	Days 1–10
Amoxicillin[c]	1 g	bid	Days 1–5
Clarithromycin	250–500 mg	bid	Days 6–10
Metronidazole[c]	250–500 mg	bid	Days 6–10
Salvage Therapy			
Bismuth subsalicylate[d]	525 mg	qid	14 days
Metronidazole[c]	500 mg	qid	14 days
Tetracycline	500 mg	qid	14 days
PPI	Standard dose[a]	Daily or bid[a]	14 days
Or			
PPI	Standard dose[a]	bid[a]	14 days
Amoxicillin[c]	1 g	bid	14 days
Levofloxacin	500 mg	Daily	14 days

bid, two times a day; H_2RA, H_2 receptor antagonist; PPI, proton-pump inhibitor; qid, four times a day.

[a]Omeprazole 20 mg bid, lansoprazole 30 mg bid, pantoprazole 40 mg bid, rabeprazole 20 mg bid, esomeprazole 20 mg bid.

[b]Although 7- to 10-day regimens may provide acceptable eradication rates, the preferred treatment duration in the United States is 14 days.

[c]Use amoxicillin in non–penicillin-allergic individuals; substitute metronidazole for amoxicillin in true penicillin-allergic patients.

[d]Pylera, a prepackaged U.S. Food and Drug Administration (FDA)-approved *Helicobacter pylori* regimen, contains bismuth subcitrate potassium (biskalcitrate) 140 mg as the bismuth salt in place of bismuth subsalicylate, metronidazole 125 mg, and tetracycline 125 mg per capsule. The patient is directed to take three capsules per dose with each meal and at bedtime. A standard dose of a proton-pump inhibitor (PPI) is added to the regimen and taken twice daily. All medications are taken for a 10-day period.

[e]See Table 23-1 for standard peptic ulcer healing dosage regimens.

[f]Requires validation in the United States.

(Lamont JT. Treatment regimens for Helicobacter pylori in adults. *UpToDate*. UpToDate; 2020. Accessed November 11, 2020. www.uptodate.com)

Drug regimens used to treat and prevent NSAID-induced ulcers are identified in **Table 23-1**. Patients with NSAID-induced ulcers should be tested to determine their *H. pylori* status. If the patient is *H. pylori* negative, the NSAID should be discontinued, and treatment should be initiated with antiulcer medications. The duration of treatment should be extended if the NSAID is continued. Prophylactic co-therapy with a PPI or misoprostol, or switching to an

NSAID with greater COX-2 selectivity, is recommended for patients at risk for exhibiting ulcer-related upper GI complications.

CASE 23-1

QUESTION 1: R.L. is an otherwise healthy 45-year-old male who works in a high-stress job as an air traffic controller at a major airport. He reports 2 weeks of "burning stomach pain," sometimes accompanied by "indigestion and bloating." The pain initially occurred several times a day, usually between meals, and sometimes awakened him at night, but it has increased in frequency during the past week. Initially, the pain was temporarily reduced by food or antacids. Last week, R.L. tried an OTC H_2RA that "lasted longer," but did not provide adequate symptom relief. R.L. states that he experienced a similar type of pain about 12 years ago when he was treated with omeprazole for a suspected peptic ulcer. He has smoked one pack of cigarettes daily for the past 20 years, has an occasional glass of red wine with dinner, and usually drinks four to six cups of caffeinated coffee throughout the day. R.L. takes acetaminophen when needed for occasional headaches and a daily multivitamin, but denies the use of any other OTC or prescription medications, including NSAIDs and the previous use of clarithromycin or metronidazole. He denies nausea, vomiting, anorexia, weight loss, and changes in stool consistency or color. A review of other body systems is noncontributory. He has no known food or drug allergies.

Physical examination is normal except for epigastric tenderness on palpation of the upper abdomen. Vital signs include a temperature of 98.8 °F (37.11 °C), blood pressure of 132/80 mm Hg, and a heart rate of 78 beats/minute. Pertinent laboratory values include the following:

Hgb, 14.0 g/dL
Hct, 44%
Stool guaiac test, negative
All other laboratory values are within normal limits.

What signs and symptoms are suggestive of a recurrent peptic ulcer?

HELICOBACTER PYLORI–RELATED PEPTIC ULCER

The diagnosis of PUD cannot be made based on symptoms alone, and requires visualization of the ulcer crater because the symptomology, severity of pain, and timing of the pain (eg, seasonal,

intermittent, or pain-free periods lasting from weeks to years) can differ for each patient and encompass a wide variety of symptoms. Most patients with PUD present with abdominal pain that is epigastric and often described as burning or gnawing, whereas others describe abdominal discomfort, fullness, or cramping. Epigastric pain, however, does not necessarily correlate with an ulcer because patients with ulcer-like symptoms may have NUD, and asymptomatic patients may have an NSAID-induced ulcer; heartburn, bloating, and belching may accompany the pain. Ulcer pain typically occurs during the day, but can also awaken the patient from sleep (nocturnal pain). In patients with a duodenal ulcer, epigastric pain frequently occurs between meals and is often relieved by food, but this varies from patient to patient. Alternatively, food may precipitate or accentuate pain in patients with a gastric ulcer.

Antacids and antisecretory medications usually provide relief of ulcer pain in most patients. Pain usually diminishes or disappears during treatment, but epigastric pain after healing often suggests an unhealed or recurrent ulcer. Changes in the character of the pain may suggest the presence of complications. Nausea, vomiting, anorexia, and weight loss are more common with gastric ulcer, but may also be suggestive of ulcer-related complication.

CASE 23-1, QUESTION 2: R.L. underwent EGD, which revealed a single 0.5-cm ulcer in the duodenal bulb. The ulcer base was clear without evidence of active bleeding. Antral gastritis was biopsy positive for *H. pylori.* What risk factors may have contributed to ulcer recurrence in this patient?

R.L. indicates that he had a similar type of abdominal pain about 12 years ago for which he was treated with omeprazole for a suspected peptic ulcer. When conventional antiulcer therapy (ie, PPI) is discontinued after ulcer healing, the ulcer tends to recur. The most important etiologic factors that influence ulcer recurrence are *H. pylori* infection and NSAID use. It is not known whether R.L. underwent testing for *H. pylori* 12 years ago. The patient denies the use of OTC and prescription NSAIDs. The long-term use of

maintenance therapy with a conventional antiulcer medication (**Table 23-1**) to maintain remission after initial ulcer healing was standard practice for years, and may have been an option for this patient at the time.[103] However, successful eradication of *H. pylori* (in a patient who is *H. pylori* positive) cures the infection, heals the ulcer, and eliminates the need for long-term maintenance therapy in most patients.[95,103]

Other factors, such as cigarette smoking, psychological stress, and diet, may have contributed to ulcer recurrence in this patient. There is strong epidemiologic evidence indicating that cigarette smoking is a major risk factor for PUD and that the risk is proportional to the number of cigarettes smoked per day.[93] Although cigarette smoking exacerbates PUD, there is insufficient evidence to conclude that it causes a peptic ulcer; however, it is hypothesized that smoking or nicotine might provide an environment for *H. pylori* infection.

R.L. works as an air traffic controller, which is a high-stress job. The importance of psychological stress and how it affects PUD is complex and multifactorial. Results from controlled trials are conflicting, and have failed to demonstrate a cause-and-effect relationship.[93,103] However, the clinical observation of patients with ulcer having high-stress jobs and a stressful lifestyle suggest that they are adversely affected.

Caffeine-containing coffee, tea, and cola beverages, constituents in decaffeinated coffee or tea, caffeine-free carbonated beverages, and alcoholic beverages, such as beer and wine, all increase gastric acid secretion; however, there is no evidence that they increase the risk of PUD. Certain foods (eg, spicy) may cause dyspepsia or worsen ulcer symptoms, but do not cause peptic ulcers. In high concentrations, alcohol is associated with acute gastric mucosal damage and upper GI bleeding, but there is insufficient evidence to confirm that alcohol causes ulcers.[93] Dietary restrictions and bland diets do not alter the frequency of ulcer recurrence.

CASE 23-1, QUESTION 3: What are the goals of therapy when treating this patient?

The goals of therapy in an *H. pylori*–positive patient with an active ulcer, a previously documented ulcer, or a history of an ulcer-related complication are to render the patient asymptomatic, heal the ulcer, eradicate the infection, and cure the disease. Treatment should be effective, well-tolerated, easy to comply with, and cost-effective. Drug regimens should have an eradication rate of at least 80% (intention-to-treat [ITT]) or 90% (per protocol analysis) and should minimize the potential for antimicrobial resistance.[122]

Primary Treatment for *Helicobacter pylori* Infection

Case 23-1, Question 4: What factors should be taken into consideration when selecting a first-line eradication regimen? What are the therapeutic options for first-line *H. pylori* eradication in the United States? Which is the preferred *H. pylori* eradication regimen for R.L.?

The selection of a first-line *H. pylori* eradication regimen should be based on proven effectiveness, and should take into consideration antibiotic combinations that permit second-line treatment (if necessary) with different antibiotics, treatment duration, the likelihood of antibiotic resistance, and the ability to adhere to the drug regimen. The antibiotics that have been most extensively studied in the United States and found to be effective in various combinations include clarithromycin, amoxicillin, metronidazole, and tetracycline (**Table 23-6**).[93,95,103]

Current treatment guidelines in the United States and Europe recommend two first-line eradication therapy combinations for patients with an *H. pylori*–positive peptic ulcer: standard triple therapy (clarithromycin-based) for 14 days or standard quadruple therapy (bismuth-based) for 10 to 14 days (**Table 23-6**).[95] Despite these recommendations, there are recent concerns about the efficacy of these regimens because of declining eradication rates thought to be related to antibiotic resistance, particularly with

clarithromycin, and the potential for nonadherence, especially with standard quadruple therapy (see Case 23-1, Question 8).[95,123–127] Clarithromycin should be avoided where resistance rates are >15% or in patients who recently received macrolide antibiotics.[122] Controversy exists as to whether standard triple therapy should remain as first-line treatment in the United States.[95,123–127] Some clinicians believe that sequential therapy should replace the clarithromycin-based three-drug regimens because of superior eradication rates or that the bismuth-based four-drug regimen should be used exclusively as first-line treatment.[123,127] Others believe that more robust clinical trials involving a broader range of patients is needed before sequential therapy replaces standard triple therapy in the United States, and that medication adherence remains problematic with standard quadruple therapy.[95,124,125]

When combined with a PPI and clarithromycin, the inclusion of either amoxicillin or metronidazole for standard triple therapy provides similar eradication rates.[95] Amoxicillin is usually preferred initially because it is associated with little or no bacterial resistance, has fewer adverse effects, and leaves metronidazole as an option for second-line therapies.[93] Recent data suggest that eradication rates with clarithromycin-based triple therapy have been declining, with global eradication rates below 80%.[128] This low eradication rate was also observed in several meta-analyses completed in the United States and Canada when treatment with clarithromycin-based triple therapy was prescribed for 7 or 10 days. The superiority of the 14-day regimen over a 7- or 10-day treatment course has been confirmed, and is less likely to be associated with antimicrobial resistance.[95] Because of this data, when standard triple therapy is chosen, guidelines now recommend it should be given for 14 days.[95] Increasing the antibiotic daily dose or extending antibiotic treatment beyond 14 days usually does not improve eradication rates. The PPI may be extended to 28 days if needed for ulcer healing. Twice-daily dosing of the PPI appears to be more effective than is a single daily dose.[129] Pretreatment with a PPI before initiating *H. pylori* eradication does not decrease the rate of eradication.[130]

Bismuth-based quadruple therapy containing a bismuth salt, metronidazole, tetracycline, and either a PPI or an H_2RA has been advocated as first-line treatment because it usually yields satisfactory eradication rates despite increased resistance to clarithromycin.[95,127] The complexity of this regimen and the potential for increased side effects often relegate it to preferred second-line status if not previously used. However, eradication rates, tolerability, and medication adherence were reported to be similar to that of standard triple therapy when used as first-line treatment, although both regimens yielded eradication rates of <80% ITT.[131] Using a PPI instead of an H_2RA permits a shorter duration of treatment (10 vs 14 days), and may provide increased efficacy in patients with metronidazole-resistant strains of *H. pylori.*[95] Increasing the duration of quadruple therapy to 1 month does not substantially increase eradication, although the antisecretory drug may be continued for an additional 2 (PPI) or 4 weeks (H_2RA) in patients with an active ulcer.

Sequential therapy was introduced in the year 2000 as a potential alternative to standard triple and quadruple therapy, with evidence arising from small studies primarily conducted in Italy. Sequential therapy, described as a PPI and amoxicillin for 5 days followed by a PPI, clarithromycin, and an imidazole for an additional 5 days, achieved eradication rates (>80% ITT). The rationale for sequential therapy is to initially treat the patient with antibiotics that rarely promote resistance (eg, amoxicillin) to reduce the bacterial load and preexisting resistant organisms, and then to follow with different antibiotics to eradicate the remaining organisms. Although the precise mechanism for the success of sequential therapy is uncertain, the increased efficacy may be related to the number of antibiotics to which the organism is exposed. Originally, this made a compelling case to switch to sequential therapy as the preferred first-line treatment in the United States.[123–125] A meta-analysis looking at previously untreated adults comparing sequential therapy with preexisting or emerging therapies demonstrated that sequential therapy is superior to a 7-day course of the clarithromycin-based three-drug regimens.[95,123–127,132–134] However, sequential therapy was

only marginally superior to the 10-day course, not superior to the 14-day course, and not superior to 10 to 14 days of bismuth-based quadruple therapy.[126] In addition, sequential therapy is more complex than is standard PPI triple therapy because it requires a midcourse change in medications.

The therapeutic options available for the eradication of *H. pylori* should be carefully considered in each individual patient. The PPI–amoxicillin–clarithromycin regimen is an acceptable first-line management strategy for R.L. because he has not previously received clarithromycin and has no known allergies to penicillin. Posttreatment testing should be considered, but may not be necessary if R.L. remains asymptomatic. Although sequential therapy may overcome clarithromycin resistance, it is unclear, at this time, whether it would provide any increased benefit in this patient.

Patient Education

Case 23-1, Question 5: R.L. is prescribed a 14-day clarithromycin three-drug eradication regimen containing amoxicillin. What instructions should R.L. be provided regarding his medications?

R.L. should be informed of the importance of taking his medications as prescribed to minimize treatment failure and the development of antibiotic resistance. He should be advised that the PPI is an integral part of the three-drug regimen and should be taken twice daily 30 to 60 minutes before breakfast and dinner (see section on Pharmacotherapy) along with amoxicillin and clarithromycin.

R.L. should also be informed of the most common side effects associated with his treatment regimen. All antibiotics included in the *H. pylori* eradication regimens are usually associated with mild side effects including nausea, abdominal pain, and diarrhea. *C. difficile*–associated diarrhea, a serious antibiotic-related complication, occurs occasionally. Oral thrush and vaginal candidiasis (in females) may also occur. Clarithromycin and metronidazole may cause taste disturbances.

R.L., as well as all other patients receiving *H. pylori* eradication therapy, should be advised of the risk of clinically important drug–drug interactions that may occur with the medications included in their eradication regimen. Special attention should be given to metronidazole and clarithromycin (inhibitors of CYP3A4), as well as to substrates of CYP2C9 (inhibited by metronidazole).[135] Drug–drug interactions may also occur with H_2RAs and PPIs (see section on Pharmacotherapy).

Regimens for the Management of *Helicobacter pylori* Infection in Patients With Penicillin Allergies

CASE 23-1, QUESTION 6: What would have been the preferred initial *H. pylori* eradication regimen if R.L. had a documented allergy to penicillin?

Before selecting alternative therapies, R.L.'s penicillin allergy should be investigated and defined as a true penicillin hypersensitivity. There are two first-line treatment options if R.L. has a true allergy to penicillin. Metronidazole can be substituted for amoxicillin in the clarithromycin-based three-drug regimen, because similar eradication rates are achieved (**Table 23-6**).[95,136] Bismuth-based quadruple therapy may also be used, because it provides similar eradication rates.[95,131]

If R.L.'s medications included metronidazole, tetracycline, or a bismuth salt, he should be provided additional information on these medications. Metronidazole-containing regimens increase the frequency of side effects (especially when the dose is >1 g/day) and may be associated with a disulfiram-like reaction in patients who consume alcohol. Tetracycline may cause photosensitivity, and should not be used in children because it may cause tooth discoloration. Bismuth salts may cause darkening of the tongue and stool.

Regimens that substitute levofloxacin for amoxicillin in clarithromycin-based triple therapy have been used with success, although there are fewer studies supporting their efficacy.[137] The most common sequential therapy contains amoxicillin and, therefore, is not suitable for a penicillin-allergic patient.

CASE 23-1, QUESTION 7: What drug substitutions are acceptable in the standard clarithromycin-based three-drug and bismuth-based four-drug eradiation regimens?

There are insufficient data to support the substitution of ampicillin for amoxicillin, doxycycline for tetracycline, and azithromycin or erythromycin for clarithromycin. Substitution of clarithromycin 250 to 500 mg four times a day for tetracycline in the bismuth-based four-drug regimen (**Table 23-6**) yields similar results, but substitution of amoxicillin for tetracycline lowers the eradication rate and is not recommended.[93,103]

CASE 23-1, QUESTION 8: What are the most important predictors of *H. pylori* treatment outcomes, and how may they alter R.L.'s response to treatment?

The two most important factors in predicting *H. pylori* treatment outcomes are antibiotic resistance and medication adherence.[95,123,124,127] Antibiotic resistance rates are highly variable throughout the United States and the world, and thus are difficult to compare.[95,124,127] However, there is evidence that clarithromycin resistance is increasing in North America and Europe, which is thought to be the most important reason for the decreasing efficacy of clarithromycin-containing eradication regimens.[95,123,124,127] Because treatment with clarithromycin may increase the likelihood of *H. pylori* resistance, clinicians should ask about previous macrolide antibiotic use when deciding upon an eradication regimen.[95]

The clinical importance of metronidazole resistance is unclear because higher metronidazole doses and the synergistic effect of combining metronidazole with other antibiotics appear to render

resistance to metronidazole more relative.[95,124,127,135] Resistance to amoxicillin and tetracycline is uncommon. Levofloxacin is emerging as a component of eradication therapy, but there are reports of increasing resistance to fluoroquinolones.[123–127,135]

Medication adherence decreases with multiple medications, increased frequency of administration, increased duration of treatment, intolerable adverse effects, and costly drug regimens.[95,123] Although most eradication studies report >95% adherence to medications, this high rate must be questioned because it is very difficult to accurately assess the level of compliance in clinical trials where patients take their own medications.[123] In addition, medication adherence is usually more problematic in clinical practice. A longer treatment duration may contribute to nonadherence, but missed doses in a shorter regimen may also lead to failed eradication. Most bismuth-based four-drug regimens require the patient to take medications four times per day, with as many as 18 tablets or capsules total per day. The complexity of this regimen, as well as a mid-treatment change in medications with sequential therapy, should be considered when selecting an eradication regimen. Although mild side effects are common with all of the eradication regimens, some patients will experience clinically important effects that lead to discontinuation of a specific drug or of the entire regimen.

Other factors that may contribute to treatment failure include high bacterial load, the specific *H. pylori* strain, low intragastric pH, and genetic polymorphism (eg, CYP2C19 polymorphism) when PPIs are used as part of the eradication regimen.[95,124,127,135,138,139] There are limited data to suggest that smoking, alcohol consumption, and diet may negatively affect eradication.

Case 23-1, Question 9: What parameters should be monitored to determine R.L.'s response to treatment?

Testing to confirm eradication should be performed in all patients treated for *H. pylori* because of increasing rates of antibiotic resistance (**Table 23-5**).[95,122] The term *eradication* or *cure* is used

when posttreatment tests, conducted 4 weeks after the end of treatment, do not detect the organism. PPIs should be held for 1 to 2 weeks before testing to prevent false-negative results.

Upper endoscopy should only be used to confirm eradication and ulcer healing if indicated (eg, severe or frequent recurrent symptoms or current or previous ulcer complication) because the procedure is costly and invasive. When endoscopic follow-up is necessary, testing to prove eradication includes a biopsy for the rapid urease test and histology (**Table 23-5**). Ulcer healing can also be confirmed at that time.

Secondary or Rescue Therapy for *Helicobacter pylori* Infection

Case 23-1, Question 10: What other drug regimens can be used if R.L. fails clarithromycin-based triple therapy? What regimens can be used when secondary treatment fails?

All initial eradication regimens require that there be an effective second-line treatment. Eradicating *H. pylori* is more difficult after initial treatment fails, and attempts to eradicate the organism are extremely variable.[95] Second-line regimens should (a) avoid using antibiotics that were used during initial therapy, (b) use antibiotics that have less problems with resistance, (c) use drugs that have a topical effect (eg, bismuth), and (d) use a 10- to 14-day treatment duration.[95,123,127,140] If R.L. was not successfully eradicated initially with the PPI–amoxicillin–clarithromycin, he should receive second-line therapy with bismuth subsalicylate, metronidazole, tetracycline, and a PPI for 10 to 14 days.[95,123,127,140,141]

Bismuth-based regimens are the most frequently used second-line treatments in the United States when standard clarithromycin-based triple therapy fails (**Table 23-6**).[95] A number of alternatives have been evaluated in small studies utilizing fluoroquinolone, rifabutin (an antibiotic used to treat tuberculosis), or furazolidone (no longer marketed in the United States).[95,123] Levofloxacin-based therapy for

14 days has shown eradication rates of 76% after clarithromycin-based triple therapy failure and 81% after sequential therapy failure.[142] The results from the levofloxacin-based clinical trials look promising and suggest that these regimens may be an alternative to second-line bismuth quadruple therapy, especially for patients who have no prior use of a fluoroquinolone.[95,123,137,140] However, increasing fluoroquinolone resistance, which appears to be easily acquired, is of concern and may limit the use of these agents for *H. pylori* eradication.[140] Various rifabutin-based regimens are effective in treating patients with *H. pylori* strains resistant to clarithromycin or metronidazole.[95,140] Regimens that include rifabutin should be the last option, and only used for patients with multiple eradication failures because of concerns about major hematologic side effects and the possibility of resistance.[140]

CASE 23-2

QUESTION 1: A.D. is a 70-year-old female who retired from teaching 5 years ago. A few days ago, she noticed black "tarry" stools and was hospitalized for an upper GI bleed most likely secondary to NSAID use. She reports of "feeling tired" and occasional dizziness for ~1 week. A.D. presents with a 5-year history of osteoarthritis for which she takes naproxen 250 mg every morning and 500 mg every evening. Other active medications include hydrochlorothiazide 25 mg daily and lisinopril 20 mg daily for hypertension, self-directed treatment with enteric-coated aspirin 81 mg daily, calcium carbonate, and a multivitamin. When questioned, she denies the use of corticosteroids, bisphosphonates, anticoagulants, clopidogrel, or selective serotonin reuptake inhibitors (SSRIs). She does not have a history of a previous ulcer or related complication. A.D. does not use tobacco or drink caffeinated beverages, but does have an occasional glass of wine. She denies epigastric pain, nausea, vomiting, anorexia, and weight loss, but notes the recent change in stool color. A review of other body systems is noncontributory other than previously indicated. There are no known food or drug allergies.

Physical examination reveals a well-developed weak female in no acute distress. The abdomen is normal, with no pain on palpation. Bowel sounds are normal, with no guarding, masses, hepatomegaly, or splenomegaly. The rectum is normal, but with guaiac-positive stool. Vital signs include a temperature of 98.9 °F (37.17 °C), blood pressure of 118/75 mm Hg, and a heart rate of 90 beats/minute. Pertinent laboratory values include the following:

Hgb, 11.0 g/dL

Hct, 35%
Blood urea nitrogen (BUN), 40 mg/dL
Serum creatinine (SCr), 1.5 mg/dL
All other laboratory values are within normal limits.

What factors placed A.D. at increased risk for experiencing an NSAID-induced ulcer and related upper GI bleeding?

NONSTEROIDAL ANTI-INFLAMMATORY DRUG–INDUCED PEPTIC ULCER

Risk factors for NSAID-induced ulcers and related complications are presented in **Table 23-3**. A.D.'s age (70 years) is an independent risk factor for NSAID-induced ulcers.[101,102] The increased incidence in older patients may be explained by age-related changes in gastric mucosal defense. A.D.'s self-treatment with cardioprotective/antiplatelet doses (81–325 mg/day) of aspirin, combined with her twice-daily NSAID use (naproxen) increases her risk of upper GI events to a greater extent than is the use of either drug alone.[101–103] The use of buffered or enteric-coated aspirin does not confer added protection from ulcer or upper GI complications.[103,112,143] The use of nonselective NSAIDs (eg, naproxen) is linked to a threefold to fourfold increase in upper GI complications, compared to a twofold to threefold increase with selective and partially selective COX-2 inhibitors (**Table 23-4**).[110] Upper GI events can occur at any NSAID dose, including low OTC doses, and at any time during treatment.[101–103] The risk of upper GI bleeding is markedly increased when NSAIDs are taken with anticoagulants, corticosteroids, bisphosphonates, antiplatelets, or SSRIs.[35,101–103,110] Corticosteroids do not increase ulcer risk when used alone, but the risk is increased twofold in corticosteroid users who are also taking concurrent NSAIDs.[101–103] SSRIs independently increase the risk of upper GI bleeding, and although the magnitude of the risk is variable, it is increased in patients taking NSAIDs.[144,145] The pharmacologic mechanism underlying this adverse effect is

thought to be related to SSRI inhibition of platelet aggregation, which may interfere with ulcer healing, but it remains unknown if SSRIs have a direct ulcerogenic effect.[144,145] Although A.D. did not have a history of an ulcer or an ulcer-related complication before admission, the history of an NSAID-related upper GI event further increases the risk of NSAID-related GI injury.[101–103] It is uncertain whether *H. pylori* is a risk factor for NSAID-induced ulcers, but a higher incidence of PUD in *H. pylori*–positive patients taking NSAIDs suggests an additive effect, which may increase the risk of NSAID-related GI complications.[101–103]

CASE 23-2, QUESTION 2: A.D. was admitted for further evaluation and treatment. An EGD revealed two bleeding antral ulcers (0.2 and 0.4 cm), and endoscopic hemostasis was performed. An antral biopsy finding was reported to be *H. pylori* negative. All medications were discontinued before endoscopy. Oral oxycodone was instituted after endoscopy at 5 mg every 6 hours as needed to control A.D.'s arthritic pain while she was hospitalized. Consideration was given to decreasing the naproxen dose and switching to acetaminophen, a non-acetylated salicylate, or a partially selective NSAID, but none of these options were satisfactory for this patient. Treatment was initiated with a continuous infusion of IV pantoprazole for 3 days and then switched to oral pantoprazole 40 mg twice daily. A.D. was discharged on pantoprazole 40 mg daily and naproxen 250 mg in the morning and 500 mg in the evening. Hydrochlorothiazide, lisinopril, calcium carbonate, and the multivitamin were resumed upon discharge from the hospital. Will A.D.'s gastric ulcer heal if she continues to take the naproxen?

The naproxen should be discontinued, if possible, in the presence of an active ulcer in favor of alternative osteoarthritis therapy.[93,103] Despite A.D. being discharged on naproxen, a PPI such as pantoprazole is the preferred treatment to heal A.D.'s gastric ulcer because its potent acid suppression provides a more rapid rate of ulcer healing (4 weeks) and symptom relief than does an H_2RA or sucralfate (6–8 weeks).[93,101,103] Because A.D. will be continuing the naproxen, the duration of PPI therapy should be extended from 4 weeks to 8 to 12 weeks, because continuing the offending NSAID will interfere with ulcer healing.[93,103] Cardiovascular risk and the need for low-dose aspirin must be determined by the patient's primary

care physician or cardiologist, and, if not needed, the aspirin should be discontinued. Three large randomized control trials were conducted in patients with diabetes, elderly patients, and patients without diabetes at moderately increased cardiovascular risk to interpret the benefits versus risks of aspirin in primary prevention; all showed significantly elevated bleeding rates compared to placebo, with only marginal benefit seen in patients with diabetes.[146–148] Updated guidelines for the primary prevention of cardiovascular disease advocate against the use of low-dose aspirin in A.D. because of her age and associated bleeding risk that outweigh the potential benefits; its use in secondary prevention is still well documented.[148] Also, it may be advisable to continue low-dose aspirin after endoscopic hemostasis in patients at elevated cardiovascular risk.[93,149] Of note, the risk of GI bleed is not reduced by substituting clopidogrel for low-dose aspirin.[35,102]

CASE 23-2, QUESTION 3: Which ulcer-healing regimen would be recommended if A.D. was reported to be *H. pylori* positive?

All patients with NSAID-induced GI events should be tested for *H. pylori* (**Fig. 23-4**). An eradication regimen (either clarithromycin-based triple therapy or bismuth-based quadruple therapy) is recommended in an *H. pylori*–positive patient with an active ulcer who is also taking an NSAID. One reason for this is that it is not possible to determine whether the *H. pylori,* the NSAID, or both actually caused the ulcer. If an individual is tested and found to be *H. pylori* positive, he or she should be offered eradication therapy whether or not there is a documented ulcer. The selection of a specific regimen (Table 23-6) depends on a number of factors, including whether the individual is allergic to penicillin.

Strategies to Reduce the Risk of Nonsteroidal Anti-inflammatory Drug–induced Peptic Ulcers

CASE 23-2, QUESTION 4: Three months later, A.D. returned to her gastroenterologist for a follow-up EGD, which confirmed that the gastric ulcers were healed. On return to her primary care physician, the pantoprazole was changed to famotidine 20 mg twice daily, and the patient was advised to discontinue low-dose aspirin. Current medications include naproxen 250 mg in the morning and 500 mg in the evening, hydrochlorothiazide 25 mg daily, lisinopril 20 mg daily, calcium carbonate, and multivitamins. What pharmacologic options are available to reduce the risk of an NSAID-induced ulcer now that A.D.'s initial ulcer is healed and that she continues to take the naproxen?

Strategies to reduce the risk of NSAID-induced ulcers and upper GI complications during continued NSAID use in patients with an ulcer history include co-therapy with a PPI or misoprostol, the use of a COX-2 inhibitor, or various combinations of a PPI, misoprostol, and a COX-2 inhibitor.[93,101–103,105,108,113] All PPIs, when used in standard doses, are effective for this indication. Standard H_2RA doses should not be recommended as prophylactic co-therapy to reduce the risk of NSAID ulcers because they are not effective in reducing the risk of gastric ulcers, which is the most common ulcer associated with NSAIDs; higher H_2RA doses reduce the risk of gastric and duodenal ulcer, but are less effective than are standard PPI doses (**Table 23-1**).[101–103] Famotidine 20 mg twice daily may be an alternative to a PPI in patients at risk who are taking low-dose aspirin,[150] but comparative trials with PPIs are needed to support the use of standard-dose H_2RAs for this indication. There are no studies that have evaluated the use of H_2RAs in reducing the risk of ulcer-related upper GI complications.

Misoprostol reduces the risk of NSAID-induced gastric and duodenal ulcers as well as the risk of upper GI complications in high-risk patients.[101–103,149] Initially, the recommended dose was 200 μg four times daily, but diarrhea and abdominal cramping limited its use. A lower daily dose of 600 μg/day should be used because it reduces GI side effects and is comparable in efficacy; dose reductions to 400 μg/day or less minimize GI side effects, but compromise gastroprotective effects.[102,103] When used as co-therapy, misoprostol

and PPIs have comparable efficacy in preventing gastric ulcer, but PPIs have fewer side effects.[102,103]

Two large randomized clinical trials compared the GI safety in patients taking COX-2 inhibitors versus nonselective and partially selective NSAIDs, and reported a reduction of 50% to 60% in upper GI events with the COX-2 inhibitors.[151,152] A 6-month trial of celecoxib in patients who were not taking low-dose aspirin revealed a statistically lower rate of ulcer complications when compared with that of ibuprofen or diclofenac,[152] but evaluation at 1 year found no GI safety advantage among those taking celecoxib.[102] Further, a post hoc analysis at 6 months indicated that patients taking celecoxib and concomitant cardioprotective doses of aspirin had a rate of upper GI events similar to those taking either diclofenac or ibuprofen, thus negating the beneficial effects of celecoxib.[152] This explains why celecoxib contains the same GI warnings as the nonselective and partially selective NSAIDs (**Table 23-4**).[153]

Because A.D. continues to take naproxen, she remains at high risk for another NSAID-related complication even though gastric ulcer healing was confirmed. Co-therapy with a PPI or misoprostol is preferred for this patient because both are effective in reducing the risk of NSAID-related upper GI events. A.D.'s osteoarthritis is well controlled with naproxen, so there is no need to switch her to celecoxib or another more costly NSAID. Combining PPI therapy with misoprostol is not necessary, but some physicians prefer to use combination therapy for older patients with multiple risk factors. Standard H_2RA doses (eg, famotidine 20 mg bid) should not be used as prophylactic co-therapy for A.D. because they are not effective in reducing the risk of NSAID-related gastric ulcer. Although higher H_2RA doses (eg, famotidine 40 mg bid) reduce the risk of gastric ulcer, they are less effective than is a PPI. Famotidine should be discontinued, and a standard PPI prophylaxis dose should be instituted (eg, pantoprazole 40 mg daily). All PPIs, when used in standard doses, are effective for this indication, but A.D.'s out-of-pocket cost should be taken into consideration when selecting a PPI.

Cyclooxygenase-2 Inhibitors and Cardiovascular Toxicity

Case 23-2, Question 5: What is the concern regarding the use of COX-2 inhibitors and the risk of cardiovascular toxicity?

The risk of cardiovascular events in patients taking COX-2 inhibitors increases with a number of factors, including increased COX-2 selectivity, higher doses, a longer duration of treatment, and preexisting cardiovascular risk.[102,103,153–155] Although ulcers and related GI complications were less likely with rofecoxib than with naproxen in the vioxx gastrointestinal outcomes research study (VIGOR) trial, the number of myocardial infarctions and thrombotic strokes were increased with rofecoxib.[151] Similar cardiothrombotic events were observed in other rofecoxib studies of longer duration.[156] In 2004, rofecoxib was withdrawn from the U.S. market, and soon thereafter valdecoxib was withdrawn amid concerns about cardiovascular risk.[102]

The cardiovascular safety of celecoxib has been evaluated, but the risk of myocardial infarction and thrombotic stroke is less certain.[102,157] Although there was no difference in cardiovascular events when celecoxib was compared with diclofenac and ibuprofen in the celecoxib Long-term Arthritis Safety Study (CLASS) trial,[152] cardiovascular events were significantly higher in a clinical trial where patients were taking higher doses of celecoxib (400 mg twice daily).[158] Similarly, no difference in cardiovascular events was noted when comparing moderate celecoxib doses to below standard doses of ibuprofen and naproxen in treating arthritis, although a dose-dependent risk remains likely.[157] Emerging data has suggested that celecoxib actually has a safer cardiovascular profile than does ibuprofen, comparable to naproxen, while demonstrating less GI and renal toxicity than do both ibuprofen and naproxen; when coadministered with cardioprotective doses of aspirin, similar results were seen.[159] Celecoxib remains available in the United States, but the underlying cardiovascular risk of the patient must be assessed

when considering the use of this drug. The lowest effective celecoxib dose should always be used for the shortest duration of time.[153]

The risk of cardiovascular events is also increased in patients taking nonselective and partially selective NSAIDs, with the possible exception of naproxen.[102,103,160–162] Naproxen is usually the preferred NSAID, especially in patients with increased cardiovascular risk.[102,103,160–162] If possible, NSAIDs and COX-2 inhibitors should be avoided in patients at very high GI and cardiovascular risk.[102] Consideration should be given to using less risky therapeutic options including acetaminophen, tramadol, or narcotics.[163] Thus, the selection of a drug regimen to reduce the risk of NSAID ulcers and GI complications should not only be based on the GI safety of the NSAID or COX-2 inhibitor but must also be weighed against the cardiovascular risk of each patient.[102,103,162]

Stratification of Future Risk for Nonsteroidal Anti-inflammatory Drug–Induced Peptic Ulcers

Case 23-2, Question 6: How does a COX-2 inhibitor compare with a PPI and a nonselective or partially selective NSAID when used to decrease ulcer risk and related complications? Have any studies evaluated GI safety in patients taking a COX-2 inhibitor plus a PPI?

There have been very few randomized controlled trials in *H. pylori*–negative patients at high risk for NSAID-related complications that compared the combined therapy of celecoxib with a PPI versus a partially selective NSAID with a PPI or celecoxib alone.[102,164,165] Results from these trials suggest that in high-risk, *H. pylori*–negative patients, combined therapy with a COX-2 inhibitor and PPI may be more efficacious than is a partially selective NSAID plus a PPI or celecoxib monotherapy in reducing NSAID-related ulcer complications. Combining a COX-2 inhibitor with a PPI may be considered in very high-risk patients; however, long-term outcomes beyond 1 year are unclear based on available evidence.[102,164,165]

Case 23-2, Question 7: What factors should be considered when evaluating management strategies for patients at risk for experiencing an NSAID-induced ulcer? What risk reduction strategies are considered acceptable for A.D.?

Strategies to reduce the risk of NSAID ulcers and related complications depend on the assessment of upper GI (**Table 23-3**) and cardiovascular risks. Although there are no universally accepted definitions, the levels of risk can be arbitrarily stratified into low, moderate, and high GI risk and low or high cardiovascular risk.[102,103] High cardiovascular risk implies a physician-recommended requirement for low-dose aspirin to prevent serious cardiothrombotic events.[102] In general, individuals younger than age 65 years, and those taking NSAIDs in the short term who do not require low-dose aspirin, are considered to be at low GI and cardiovascular risk and usually do not require GI risk reduction therapy.[102,103]

Patients at moderate GI risk typically have one to two risk factors that include age older than 65 years, a history of a prior uncomplicated ulcer, treatment with high-dose NSAIDs, or the concurrent use of aspirin (including low-dose), corticosteroids, or anticoagulants. The recommended risk reduction strategy in this group is co-therapy with either a PPI or misoprostol, but misoprostol is usually considered a secondary option because of its GI adverse events and the need for more frequent daily dosing.[102,103] If the patient requires low-dose aspirin, naproxen is the NSAID of choice. Although celecoxib provides gastroprotective effects similar to that of a nonselective or partially selective NSAID plus a PPI or misoprostol, its use may be limited by cost, prescription-only availability, and concerns related to myocardial infarction and thrombotic events.[102]

Patients at very high GI risk include those with a prior history of an ulcer-related complication or multiple (more than two) risk factors (**Table 23-3**).[102,103] If cardiovascular risk is low, alternative therapies such as oxycodone are preferred, but a COX-2 inhibitor plus a PPI or misoprostol may be used.[102] Although it is best to avoid an NSAID if the patient had a complicated ulcer, some physicians will continue the same NSAID that provided the most effective anti-inflammatory

effect. This should be done with extreme caution and with maximally effective co-therapy. All COX inhibitors should be avoided in patients at high GI risk and high cardiovascular risk, and alternative therapy should be used.[102,103]

Patients such as A.D., who have a history of a recent ulcer and related upper GI bleed, are at high risk for future NSAID-related ulcers and complications and require an effective risk reduction strategy. In addition, A.D. has other factors that contribute to her high-risk status, including her age (70 years) and the continued use of a nonselective NSAID (naproxen). Famotidine should be discontinued immediately, and A.D. should be switched to an evidence-based risk reduction regimen. If celecoxib is used, the risk of cardiovascular effects must be weighed against the gastroprotective benefits, especially because A.D. has a history of hypertension. If A.D. had renal dysfunction (specifically creatinine clearance <30 mL/minute), NSAIDs and COX-2 inhibitors should be avoided, and the patient should be treated with other analgesics (eg, tramadol, narcotics), keeping in mind that NSAIDs and COX-2 inhibitors are associated with fluid retention, hypertension, and renal failure. Although switching naproxen to celecoxib plus a PPI or continuing the oxycodone may be preferred by some, the selection of the optimal strategy for a high-risk patient such as A.D. is debatable and should take into consideration the risks, benefits, patient preferences, continued analgesic relief, and cost of treatment. Co-therapy with a PPI or misoprostol is an acceptable risk reduction strategy given A.D.'s GI and cardiovascular risk. Combination therapy of celecoxib and PPI may represent the greatest GI risk reduction and may be considered in this patient.

Case 23-2, Question 8: What information should be conveyed to A.D. regarding the combined use of OTC aspirin and NSAIDs?

Remind A.D. that her physician has recommended that she discontinue taking the enteric-coated aspirin and that she should not restart it without his/her consent. Explain to A.D. that enteric-coated

aspirin may protect against the topical mucosal damage in the stomach and minimize dyspepsia, but the enteric coating does not prevent an ulcer. Even low-dose aspirin (eg, 81 mg/day) is capable of causing an ulcer, especially when used in conjunction with an NSAID (naproxen). Buffered aspirin may cause less dyspepsia, but buffering does not prevent ulcers. Taking food, milk, or an antacid with aspirin or NSAIDs may minimize dyspepsia, but does not prevent an ulcer. Inform A.D. that she should not take OTC NSAIDs in conjunction with her naproxen unless advised to do so by her physician, because combining NSAIDs will increase the risk of ulcers and GI bleeding. Advise A.D. that even though NSAIDs available for self-treatment may have different generic names (eg, ibuprofen, naproxen), they all belong to the same drug class and have similar side effects.

Case 23-2, Question 9: A.D.'s physician decides to maintain her on naproxen, but changes the famotidine to lansoprazole 30 mg daily. What instructions should you provide A.D. regarding her medications?

A.D. should be advised of the major signs and symptoms of upper GI bleeding and cardiovascular disease and what action should be taken if these signs or symptoms develop. She should be instructed to take the lansoprazole daily, 30 to 60 minutes before breakfast, and continue taking naproxen twice daily. The importance of adhering to PPI co-therapy must be stressed, especially because A.D. may not have accompanying dyspeptic or ulcer-like symptoms. There is a strong relationship between the level of adherence to gastroprotective medication and the risk of ulcers and serious GI complications in patients such as A.D. who are high-risk NSAID users.[166] Older patients, such as A.D., who are at risk for osteoporosis and hip fractures and who require long-term PPI therapy should be counseled to take age-related recommended doses of a calcium salt and vitamin D and have periodic bone density examinations (see section on Pharmacotherapy of Drugs Used to Treat Acid-Related Disorders).

CASE 23-2, QUESTION 10: What parameters should be monitored to determine A.D.'s response to treatment?

High-risk patients such as A.D. who continue to take an NSAID daily should be closely monitored for upper abdominal pain and signs or symptoms associated with bleeding, obstruction, or perforation. The presence of upper abdominal pain or a change in the severity of the pain may suggest an upper GI complication. Every effort should be made to monitor A.D.'s compliance with her PPI regimen because of the strong relationship between nonadherence and the risk of upper GI complications in high-risk NSAID users.

ZOLLINGER–ELLISON SYNDROME

ZES is an uncommon gastric acid hypersecretory disease characterized by severe recurrent peptic ulcers that result from a gastrin-producing tumor (gastrinoma).[141,167] The primary tumor is usually located in the duodenum or pancreas, but other locations (eg, mesenteric lymph nodes, spleen, stomach, liver) have been described.[141,167] Although most gastrinomas occur sporadically, ~25% occur in association with multiple endocrine neoplasia type 1 (MEN 1), which is an autosomal dominant inherited syndrome.[167] Most gastrinomas are malignant and tend to be slow growing, but a small number grow and metastasize rapidly to the regional lymph nodes, liver, and bone. Abdominal pain is the most predominant symptom, and is usually related to persistent peptic ulcers, which are less responsive to antisecretory therapy. Duodenal ulcers occur most often, but ulcers may also occur in the stomach or jejunum. Diarrhea, which is present in more than half of patients, may precede ulcer symptoms and results from massive gastric acid hypersecretion, which activates pepsinogen and contributes to mucosal damage.[141,167] Steatorrhea may also occur, and results from inactivation of pancreatic lipase by low duodenal pH resulting from

excessive acid load.[167] This leads to the precipitation of bile acids, which, in turn, reduces micelle formation necessary for fatty acid absorption. Vitamin B_{12} deficiency may develop secondary to malabsorption related to reduced intrinsic factor activity. GERD often occurs, and is complicated by esophageal ulcers and strictures. Other symptoms include nausea, vomiting, upper GI bleeding, and weight loss. Upper GI bleeding is related to duodenal ulceration and may be the presenting symptom.

Epidemiology

The incidence of ZES in the United States is 0.1% to 1.0% among patients with duodenal ulcers.[167] The majority of patients are diagnosed between the ages of 30 and 50 years, with males being slightly more affected than are females.[167] The morbidity and mortality of ZES have decreased because of improved medical and surgical management.

Pathophysiology

The pathophysiology of ZES is related to a non-β islet cell gastrin-secreting tumor that stimulates the parietal cells of the stomach to hypersecrete gastric acid.[141,167] Large amounts of gastrin are produced by the gastrinoma cells, usually resulting in a profound hypergastrinemia. The gastric parietal cell mass is expanded in response to the trophic effects of hypergastrinemia and causes an increase in basal and stimulated acid output. Hypersecretion of gastric acid results in severe mucosal ulceration, diarrhea, and malabsorption, and is responsible for the signs and symptoms associated with ZES.

Clinical Assessment and Diagnosis

The diagnosis of ZES is established when the fasting serum gastrin is >1000 pg/mL and the BAO is >15 mEq/hour in patients with an

intact stomach (or >5 mEq/hour in the postgastric surgery patient) or when hypergastrinemia is associated with a gastric pH value <2.[167] When serum gastrin is between 100 and 1000 pg/mL and gastric pH is <2, a provocative test (secretin or calcium) is recommended to assist in the diagnosis. Imaging techniques are performed to localize the tumor, and are useful in evaluating metastatic disease. Upper endoscopy is performed to confirm mucosal ulcerations. The use of PPIs may mask the clinical presentation and complicate the diagnosis.[141]

Treatment

The goal of treatment for ZES is to pharmacologically control gastric acid secretion and to surgically resect the tumor, if possible. Oral PPIs are the drugs of choice for controlling acid secretion because of their potent and prolonged antisecretory effect. Treatment should be initiated with omeprazole 60 mg/day or an equivalent oral dose of lansoprazole, pantoprazole, esomeprazole, or rabeprazole (see **Table 23-1**), and should be titrated to maintain a BAO <10 mEq/hour (1 hour before next dose) in patients with no complications or <5 mEq/hour in patients with complicated disease.[167] Once adequate control of acid secretion has been achieved, the daily PPI dose should be gradually reduced and administered every 8 to 12 hours. In most patients, an omeprazole dose of 60 to 80 mg/day reduces the BAO to target levels. IV PPIs should be reserved for those patients who are not able to take oral medications. H_2RAs are no longer used to treat ZES, despite proving efficacy at higher doses, because they are not as effective as PPIs (see **Table 23-1**).

Somatostatin analogs are used with varying success to treat gastrinomas, but they are only available parenterally and rarely used as first-line treatment.[167] Octreotide, a synthetic somatostatin analog, inhibits gastric acid secretion and decreases serum gastrin concentrations; however, its subcutaneous route of administration, frequent dosing, and side effect profile (abdominal pain, diarrhea, gallstones, and pain at the injection site) make it less desirable for

use in treating ZES. The long-acting depot formulation of octreotide can be administered less frequently, and may be useful in controlling temporal growth. Patients with metastatic gastrinomas can be treated with chemotherapeutic agents to inhibit tumor growth, or may require resection of the tumor. Localization and surgical removal of the gastrinoma should be considered in all patients unless widespread metastases exist.

GASTROESOPHAGEAL REFLUX DISEASE

GERD is a common acid-related GI disorder associated with a wide array of symptoms, the most frequent of which is heartburn and acid regurgitation. Gastroesophageal reflux (GER) is defined as the retrograde passage of gastric contents from the stomach into the esophagus. It is primarily the result of transient relaxation of the LES. When the LES is relaxed, the esophagus is exposed to small amounts of acidic stomach contents. This normal physiologic event occurs many times throughout the day in healthy individuals.[168–170] Protective mechanisms, such as esophageal peristalsis and bicarbonate-rich saliva, quickly return the acidic pH to normal. GERD develops when alterations in reflux result in symptoms, mucosal injury, or both.[62] Esophageal injury occurs with continued exposure of the mucosa to gastric acid and results in inflammation that can progress to ulceration (erosive esophagitis).[168,171] Complications associated with long-standing GERD include esophageal strictures, Barrett metaplasia (replacement of normal esophageal squamous epithelium by specialized intestinal-like columnar epithelium), and adenocarcinoma of the esophagus.[3] Male sex and advanced age (males and females) are associated with an increase in the prevalence of esophageal complications, presumably as a result of refluxed acidic contents damaging the mucosa over time.[168]

Epidemiology

GERD is a chronic disease that affects patients across all age groups, with equal distribution between males and females.[3] In Western populations, 25% of patients report heartburn monthly, 12% weekly, and 5% describe daily symptoms, whereas symptoms of regurgitation were reported in 16% of patients.[172] GERD is the second most common GI disease diagnosed in the outpatient setting.[1] It has been estimated that 7% of the U.S. population has complicated GERD associated with erosive esophagitis; however, this finding is difficult to validate because most patients do not undergo diagnostic esophageal endoscopy.[3] Many patients with erosive esophagitis are asymptomatic on diagnosis, which suggests that symptoms do not correlate with the degree of esophageal injury. Up to 75% of patients who undergo endoscopic procedures as a result of symptoms associated with GERD have normal esophageal findings.[173] These patients are identified as having functional heartburn, nonerosive reflux disease (NERD), or endoscopy-negative reflux disease (ENRD). Other patients with GERD have symptoms that occur outside the esophagus, which are considered atypical or extraesophageal manifestations of GERD. Extraesophageal manifestations may be present with or without accompanying typical symptoms (eg, heartburn) and have been estimated to occur in about 80% of patients with at least weekly symptoms of GERD (see section on Extraesophageal Manifestations).[174]

Childhood GERD appears to continue into adolescence and adulthood.[175] Although most infants exhibit physiologic regurgitation, or spitting up, the majority (95%) will have abatement of symptoms by 1 year of age.[176] Pregnancy has also been associated with an increased incidence of GERD, with an overall incidence of 30% to 50% depending on other risk factors and trimester. GERD can begin in any trimester, but is less likely to start in the third trimester (8% of patients).[62,177,178] The mechanisms for GERD in pregnancy are related to the hormonal effects of progesterone and estrogen, which lower LES pressure, and increase intra-abdominal pressure (see Chapter 49, Obstetric Drug Therapy, for a complete discussion

related to the management as well as the risks and benefits associated with treating GERD in the pregnant patient).[168,179]

Etiology and Risk Factors

The causes of GERD are associated with factors that increase the frequency or duration of GER leading to increased contact of the acidic refluxate with the esophageal mucosa. Risk factors associated with GERD include dietary and lifestyle factors, drugs, and certain medical and surgical conditions (**Table 23-7**).[3,169–171,180,181] These factors may precipitate or worsen GERD symptoms by lowering the LES pressure (eg, nitrates, progesterone, foods high in fat, mint, chocolate) or by having a direct irritating effect on the esophageal mucosa (eg, citrus, tomatoes, bisphosphonates). Stress reflux from increased intra-abdominal pressure has been associated with overeating, coughing, and bending or straining to lift heavy objects, as well as tight-fitting clothing.[168] Conditions such as gastroparesis, scleroderma, ZES, and long-term placement of nasogastric tubes may also be associated with GERD.[168]

Table 23-7
Risk Factors Associated With Gastroesophageal Reflux Disease

Drugs	Dietary
α-Adrenergic agonists	Foods high in fat
Anticholinergics	Spicy foods
Aspirin	Carminatives (peppermint, spearmint)
Barbiturates	Chocolate
Benzodiazepines	Caffeine (coffee, tea, colas)
β_2-Adrenergic agonists	Garlic or onions
Bisphosphonates	Citrus fruits and juices
Calcium channel blockers	Tomatoes and juice
Dopamine	Carbonated beverages
Estrogen	

Drugs	Dietary
Isoproterenol	**Lifestyle**
Iron	Cigarette/cigar smoke
Narcotics	Obesity
Nitrates	Supine body position
NSAIDs	Tight-fitting clothing
Progesterone	Heavy exercise
Potassium	
Prostaglandins	**Medical/Surgical Conditions**
Quinidine	Pregnancy
Tetracycline	Scleroderma
Theophylline	ZES
Tricyclic antidepressants	Gastroparesis
Zidovudine	Nasogastric tube intubation

NSAID, nonsteroidal anti-inflammatory drug; ZES, Zollinger–Ellison syndrome.

Pathophysiology

The pathophysiology of GERD is associated with defects in transient relaxations of the LES, esophageal acid clearance and buffering capabilities, anatomic abnormalities, mucosal resistance, and exposure of the esophageal mucosa to aggressive factors (gastric acid, pepsin, and bile salts) leading to esophageal damage.[168]

TRANSIENT RELAXATIONS OF THE LOWER ESOPHAGEAL SPHINCTER

The LES, when in a resting state, remains at a high pressure (10–30 mm Hg) to prevent the gastric contents from entering into the esophagus.[168] Pressures are lowest during the day and with meals, and highest at night.[168] Transient relaxations of the LES are short periods of sphincter relaxation that are different from those that occur with swallowing or peristalsis.[3,182] They occur as a result of vagal stimulation in response to gastric distension from meals (most common), gas, stress, vomiting, or coughing, and can persist for >10 seconds.[3] These transient relaxations of the LES are associated with virtually all GER events in healthy individuals, but account for 50% to 80% of occurrences in patients with pathogenic GERD.[3] Thus, not all transient relaxations of the LES are associated with GERD.

A small percentage of patients may also have a continuously weak and hypotensive LES (decreased LES resting tone). Stress reflux increases intra-abdominal pressure and may blow open the hypotensive LES.[3] When LES pressures remain constantly low, the risk of serious complications (eg, erosive esophagitis) increases dramatically. Scleroderma, which is related to fibrosis of smooth muscle, may reduce LES tone and increase the potential for GERD.[168]

ESOPHAGEAL ACID CLEARANCE AND BUFFERING CAPABILITIES

Although the number of reflux events and quantity of refluxate are notable, it is the duration of time the mucosa is in contact with these noxious substances that determines esophageal damage and complications. More than 50% of patients diagnosed with severe esophagitis have decreased acid clearance from the esophagus.[168] Peristalsis is the primary mechanism by which acid refluxate is removed from the esophagus. Other mechanisms include swallowing, esophageal distension in response to refluxate, and gravity (which is only effective when the patient is in an upright position).

Saliva plays an important role in the neutralization of gastric acid within the esophagus. Its bicarbonate-rich content buffers the residual acid that remains in the esophagus after peristalsis.[168] However, saliva is only effective on small amounts of gastric acid because patients with larger volumes of acid refluxate may not have the neutralizing capacity in saliva necessary to protect the esophagus.[168] Swallowing increases the rate of saliva production and esophageal acid clearance. The reduction of swallowing that occurs during sleep is associated with nocturnal GERD. Patients with decreased saliva production (eg, elderly, patients taking medication with antimuscarinic effects, and those with certain medical conditions such as xerostomia or Sjögren syndrome) may also be at increased risk for experiencing GERD.[168]

ANATOMIC ABNORMALITIES

Hiatal hernia (protrusion of the upper portion of the stomach into the thoracic cavity because of weakening in the diaphragmatic muscles) is frequently described as a cause of GERD, but its causal relationship remains uncertain.[168] Although hiatal hernia is associated with a greater degree of esophagitis, strictures, and Barrett metaplasia, not all patients with hiatal hernia exhibit symptoms or complications. This may be related to the size of the hiatal hernia and its effect on LES pressure.[168] An increase in the size of the hernia may decrease its ability to remain below the diaphragm during swallowing, and, thus, reduces LES pressure. Hypotensive LES in combination with hiatal hernia increases the likelihood of reflux and complicated disease.[168]

MUCOSAL RESISTANCE

The capability of the esophageal mucosa to endure contact with and withstand injury from gastric refluxate (acid and pepsin) is a substantial determinate for the development of GERD. When considering the mucosal resistance within the esophagus compared with that of the stomach and duodenum, the esophagus is less resistant to damage from gastric acid.[168] However, mucosal

resistance in the esophagus is composed of many defensive factors working in tandem to prevent esophageal injury. An increase in mucosal cell thickness and intracellular junctional complexes prevents the diffusion of hydrogen ions from penetrating into the esophageal epithelium, leading to cell death.[168] The esophagus also secretes a protective mucous layer and bicarbonate.[168,183] Enhanced blood flow in response to an acidic environment within the esophagus improves tissue oxygenation, provides nutrients, and helps maintain a normal acid–base balance.[168] Esophageal injury also occurs when the concentration of acid and pepsin exceed the protection afforded by mucosal resistance mechanisms.

AGGRESSIVE FACTORS ASSOCIATED WITH ESOPHAGEAL DAMAGE

The gastric refluxate, which is composed primarily of gastric acid and pepsin, is the primary aggressive factor associated with GERD. The development and degree of mucosal damage is dependent on the pH and contents of the refluxate as well as the total exposure time of refluxate with the esophageal mucosa. A pH <4 is usually required to produce injury to the esophageal mucosa, but as the refluxate becomes more acidic, the mucosal damage is accelerated.[168] The duration of total exposure time of the esophagus to the refluxate is the primary mechanism involved in the development of GERD and its complications. The longer the duration of exposure time, the greater the possibility of severe disease, including progression to Barrett metaplasia. The addition of pepsin (which is converted from secreted pepsinogen in an acidic pH) to the acidic refluxate will markedly increase the propensity of the refluxate to compromise mucosal resistance, which increases the potential for esophageal bleeding.[168,184] Duodenogastric reflux or alkaline reflux containing bile acids and pancreatic juices may also contribute to esophagitis.[168] Because gastric and duodenogastric reflux are often concomitantly present, their actions may be additive in causing esophageal damage.

ERADICATION OF HELICOBACTER PYLORI

There is currently no data proving a causal relationship between *H. pylori* infection and GERD. In a community-based study from the United Kingdom, it was concluded that treatment for *H. pylori* infection was not associated with an increase in heartburn or other GERD symptoms.[95,184] Routine *H. pylori* testing in patients with GERD is not standard practice; if the patient is tested and found to be *H. pylori* positive, eradication is recommended (see section on Primary Treatment for *Helicobacter pylori*).[95]

Clinical Presentation

SIGNS AND SYMPTOMS

CASE 23-3

QUESTION 1: W.J. is a 39-year-old, 286.60-pound (130-kg), 66.93-inch (170-cm)-tall male who presents with indigestion. He describes a burning sensation behind his breastbone and some belching that is often associated with an acid taste in the back of his mouth. He indicates that his symptoms began a few months ago, and they only occur a few times a month, especially after eating large or spicy meals. Also, if he eats too close to bedtime, the burning keeps him up at night. He has used liquid antacids in the past for these symptoms and states they work fairly well, but he has to take frequent doses, because the symptoms return quickly. He does not take any other medications.

Which of W.J.'s symptoms are consistent with GERD?

Symptoms that are typically associated with GERD include heartburn, pyrosis (a retrosternal burning that occurs in the upper esophagus and travels up through the throat), regurgitation of gastric contents into the throat, or a combination of the three.[62,168] These symptoms may be episodic or meal related, and are often alleviated by antacids.[168] Heartburn, the most frequent typical symptom, is caused by the contact of acidic refluxate with nerve endings within the esophageal mucosa.[168] Other symptoms include water brash (salty or sour fluid occurring abruptly within the mouth), early satiety, belching, hiccups, nausea, and vomiting.[168] Worrisome symptoms

(alarm signs or symptoms) include dysphagia (trouble swallowing), odynophagia (painful swallowing), vomiting of blood, bloody or tarry stools, unexplained weight loss, and anemia.[62,168] These symptoms suggest complicated disease, such as erosive esophagitis, esophageal stricture, malignancy, or GI bleeding, and require immediate evaluation by a health care professional. Some patients, such as the elderly, may not have typical GERD symptoms, but present initially with alarm symptoms.[168,185] This is attributable in part to older patients having a reduced pain perception and a possible reduction in the acidity of the refluxate.[168] Other patients may present with only extraesophageal or atypical symptoms (see section on Treatment for the Extraesophageal Manifestations of Gastroesophageal Reflux Disease). Despite the lack of esophageal symptoms, the potential for serious esophageal damage exists, because there is no correlation between symptoms and the degree of esophageal injury.[168] W.J.'s symptoms of a burning sensation (heartburn), regurgitation soon after eating spicy or large meals, and the association of symptoms with eating a meal near his bedtime are all consistent with GERD. The fact that his symptoms are relieved by his use of antacids is also suggestive of GERD.

Treatment

THERAPEUTIC GOALS

Case 23-3, Question 2: What are the therapeutic goals for the treatment of W.J.'s GERD?

The therapeutic goals for the management of GERD are to alleviate symptoms, promote esophageal healing, prevent recurrence, provide cost-effective pharmacotherapy, and avoid long-term complications.[168] One long-term consequence is Barrett esophagus, or Barrett metaplasia, which is identified in 5% to 15% of patients with GERD upon endoscopic evaluation.[168,186,187] This premalignant condition may predispose the patient to esophageal

adenocarcinoma. Patients with Barrett esophagus have a risk of developing esophageal cancer that is 30 to 40 times higher than do patients without this disorder.[186]

NONPHARMACOLOGIC MEASURES AND SELF-DIRECTED TREATMENT

CASE 23-3, QUESTION 3: What lifestyle and dietary changes may potentially reduce W.J.'s GERD symptoms?

Lifestyle and dietary modifications comprise the initial step in managing patients with GERD (**Table 23-8**).[62,181,188,189] Strategies should be discussed with the patient and tailored to his or her specific needs. The paucity of evidence to date suggests that although many patients may benefit from these modifications, they are unlikely to completely alleviate symptoms in most patients.[62,189] Lifestyle modifications are aimed at reducing acid exposure within the esophagus by increasing LES pressure, decreasing intragastric pressure, improving esophageal acid clearance, and avoiding specific agents that irritate the esophageal mucosa. There is evidence to support several modifications that reduce esophageal gastric acid exposure and symptoms.[62,189] These include raising the head of the bed 6 to 8 inches, sleeping in a left lateral decubitus position, and weight loss, which also decreases intragastric pressure.[62,189]

Table 23-8
Dietary and Lifestyle Modifications Used to Manage Gastroesophageal Reflux Symptoms

Dietary	Medication	Lifestyle
Avoid foods listed in Table 23-7	Avoid medications with a potential to relax the lower esophageal sphincter or that have a direct irritant effect on the esophageal mucosa (Table 23-7)	Stop or decrease smoking/tobacco

Dietary	Medication	Lifestyle
Avoid eating large meals	Medications with the potential to irritate the esophagus should be taken with a full glass of water	Avoid alcohol
Avoid eating within 3 hours of bedtime		Lose weight[a]
		Elevate the head of bed 6–8 inches or use a foam wedge[a]
		Sleep in the left lateral decubitus position[a]

[a]Sufficient evidence exists to support lifestyle modification.

Sources: Katz PO, Gerson LB, Vela MF. Guidelines for the diagnosis and management of gastroesophageal reflux disease. *Am J Gastroenterol*. 2013;108(3): 308–328; Benamouzig R, Airinei G. Diet and reflux. *J Clin Gastroenterol*. 2007;41:S64–S71; Kahrilas PJ. Clinical practice. Gastroesophageal reflux disease. *N Engl J Med*. 2008;359(16):1700–1707; Kaltenbach T, Crockett S, Gerson LB. Are lifestyle measures effective in patients with gastroesophageal reflux disease? An evidence-based approach. *Arch Intern Med*. 2006;166(9):965–971.

Patients with GERD symptoms should avoid foods and beverages known to trigger symptoms (see **Table 23-7**); however, the evidence suggesting benefit remains uncertain.[62,189] Individualized lifestyle and dietary modifications should be recommended to all patients with GERD symptoms. When appropriate, OTC or prescription medications should be recommended.[62]

W.J. has a body mass index (BMI) of 45, which is considered class 3 obesity. Because obesity is a large risk factor for Barrett esophagus, particularly an abnormal waist-to-hip ratio, he should be counseled to lose weight.[190] Further, he should be advised to wear loose-fitting clothing and avoid eating spicy meals that he knows will exacerbate his symptoms. He should also be advised to avoid eating

at least 3 hours before bedtime and consider raising the head of his bed 6 to 8 inches because these efforts may help decrease nocturnal symptoms.

CASE 23-3, QUESTION 4: Which OTC treatment options (if any) would you recommend for W.J.?

Many patients with mild, infrequent symptoms can be managed with OTC medications (**Fig. 23-5**).[168,191–193] First, a determination must be made as to the suitability of the patient for self-treatment. This determination is based on the absence of the following: alarm signs or symptoms, severe or frequent (2 or more days a week) heartburn lasting >3 months, presence of extraesophageal manifestations (see Case 23-5), or symptoms that persist despite appropriate drug therapy. If the patient does not meet the criteria for self-treatment, he or she should be referred for further medical evaluation.[168,192,193] OTC antacids and H_2RAs are the drugs of choice for patients with mild, infrequent heartburn; OTC PPIs should be reserved for patients who experience more frequent heartburn (see Table 23-1).[62]

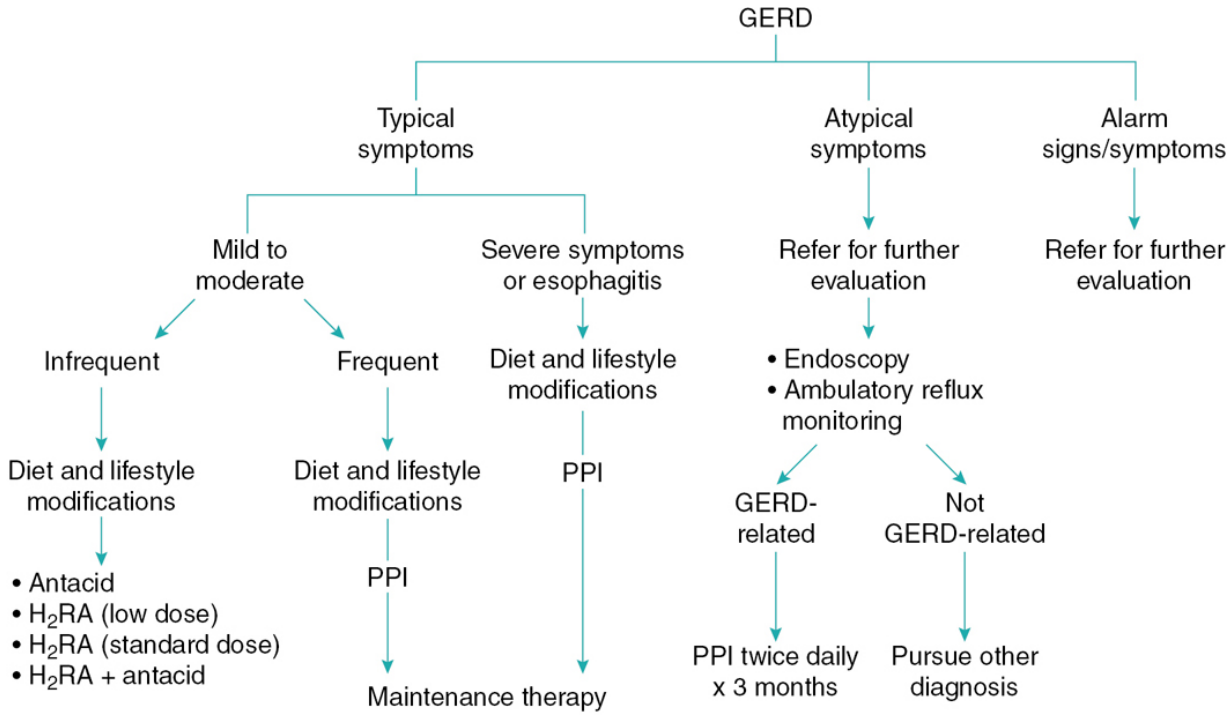

Figure 23-5 Management of GERD. GERD, gastroesophageal reflux disease; H_2RA, H_2 receptor antagonist; PPI, proton-pump inhibitor.

Antacids remain an effective option for treating mild, infrequent heartburn (occurring less than once weekly) because they rapidly (within minutes) relieve symptoms, although the duration of symptom relief only lasts about 30 minutes when taken on an empty stomach (see section on Antacids in Pharmacotherapy of this chapter).[62] They are available in tablet and liquid forms, and are usually interchangeable when used in recommended doses. Although doses can be repeated multiple times per day as needed, the maximum recommended daily dose should not be exceeded. Patients requiring frequent or regular antacid use for more than 2 weeks should be reevaluated because an H_2RA or a PPI may be needed.[62,192,193] About 20% of patients will achieve symptom relief with the use of antacids; however, they are not effective in healing erosive esophagitis, nor do they prevent GERD.[3,168]

The OTC H_2RAs are indicated for mild-to-moderate infrequent GERD symptoms.[192] When compared with antacids, their onset of

symptom relief is slower, but they have a longer duration of action (up to 10 hours).[168] One benefit of the H_2RAs is that they can be used prophylactically for postprandial GERD symptoms.[168] They also have a beneficial effect on reducing nocturnal acid secretion. Tachyphylaxis (tolerance) has been reported with continued use of H_2RAs within 2 to 6 weeks of initiation, although this effect can be overcome with intermittent or as-needed use.[194] The four H_2RAs (cimetidine, famotidine, ranitidine, nizatidine) are interchangeable when used in recommended doses (see Table 23-1). When used for self-treatment, the H_2RA dose should not exceed two doses per day, and the treatment duration should not exceed 2 weeks. Use beyond 2 weeks should be under the care of a health care provider.[168]

OTC PPIs are potent inhibitors of gastric acid, and are indicated for use in patients with frequent heartburn (≥2 days a week) or in patients who have failed twice-daily H_2RA therapy.[62] The onset of symptom relief is slower (2–3 hours) than it is with H_2RAs, and complete relief may not be realized until up to days after therapy initiation. PPIs are superior to H_2RAs with regard to symptom relief and duration of acid suppression. Patients should take the OTC PPIs 30 to 60 minutes before a meal (breakfast is preferable) and not take more than one dose daily for up to 2 weeks. Another course of therapy should not be taken more than every 4 months unless directed by a health care provider, because this may indicate more serious disease.[168,192,193]

W.J. is an appropriate candidate for self-treatment because his symptoms are mild, occur infrequently, and are not classified as alarm symptoms. Although antacids are an acceptable option for W.J., he has tried these and is unhappy with the frequency of dosing needed to relieve his heartburn. Because W.J. has requested a medication to specifically “prevent” meal-related symptoms, he should take an OTC H_2RA 30 to 60 minutes before eating or drinking. If symptoms remain infrequent and unrelated to meals, as-needed use of an OTC H_2RA is reasonable. He can increase the dose to twice daily if symptom relief is not optimal, and may consider

an OTC PPI if symptoms occur >2 days a week. If he continues to have symptoms beyond 2 weeks, they become more severe, or they are accompanied by alarm symptoms, he should be referred for further evaluation.

SEVERE DISEASE WITH COMPLICATIONS

CASE 23-4

QUESTION 1: L.F. is a 48-year-old female who presents to her primary care provider reporting recurrent heartburn occurring daily for the past 6 weeks. She states that the heartburn occurs frequently after meals and often wakens her at night. Lately, she has been experiencing difficulty swallowing solid foods. L.F. currently smokes two packs of cigarettes per day and likes to have two glasses of wine each night with her dinner. She states that she occasionally uses OTC ranitidine 150 mg orally up to twice daily, which temporarily relieves her symptoms.

What diagnostic modalities are available for the evaluation of her GERD?

Clinical Assessment and Diagnosis

Numerous diagnostic options exist for the evaluation of the patient with presumed GERD. The medical history should include the identification of specific symptoms and an assessment of symptom frequency, severity, and duration as well as risk factors or triggers. An empiric diagnosis can be made in the majority of patients based on the symptoms of heartburn and regurgitation. However, patients who present with severe symptoms, alarm symptoms, or long-standing GERD or who do not respond to empiric therapy warrant further diagnostic evaluation.

ACID SUPPRESSION EMPIRIC TEST

A trial of a PPI is commonly used to empirically diagnose typical GERD-like symptoms in patients without alarm symptoms or symptoms of complicated disease. Doses used in clinical trials range from 20 to 80 mg of omeprazole (or equivalent) once daily for up to 4 weeks.[168,195] If symptoms are relieved after a short trial of a PPI (7–

14 days), an empiric diagnosis of GERD may be made and other invasive and costly diagnostic methods may be avoided.[168,169,191,195,196] However, this methodology is not without its limitations. The test cannot differentiate between other acid-related disorders, such as PUD, and studies evaluating its ability to detect GERD versus other diagnostic options have been equivocal.[168,195,196]

UPPER ENDOSCOPY AND BIOPSY

Upper endoscopy, although not required to make a GERD diagnosis, is the primary diagnostic method for evaluating the esophageal mucosa for injury or cellular changes. It is usually recommended in the presence of alarm symptoms or in patients suspected to be at high risk for developing Barrett esophagus.[62] There are four primary reasons why endoscopy is performed in patients suspected of having GERD[168]: (a) to rule out significant disease (eg, adenocarcinoma of the esophagus) or complications (eg, stricture); (b) to screen for Barrett metaplasia; (c) to evaluate and grade the severity of esophagitis; and (d) to allow the provider to optimize treatment and predict the long-term course of the disease. Endoscopic grading of the esophagus is based on the level of inflammation and mucosal damage; two classification systems are used for the grading of esophagitis (**Table 23-9**).[197]

Table 23-9
Classification Systems for Endoscopically Determined Esophagitis

The Savary–Miller Classification System of Esophagitis	
Grade 0	Normal esophageal mucosa
Grade 1	Erythema or diffusely red mucosa, edema causing accentuated folds
Grade 2	Isolated round or linear erosions extending from the gastroesophageal junction upward, not involving entire circumference
Grade 3	Confluent erosions extending around entire circumference or superficial ulceration without erosions
Grade 4	Complicated cases; erosions as in grade 3 plus deep ulcerations, strictures, or columnar epithelium-lined esophagus

The Savary–Miller Classification System of Esophagitis	
Grade 5	Presence of Barrett metaplasia
The Los Angeles Classification System of Esophagitis	
Grade A	One (or more) mucosal break no longer than 5 mm that does not extend between the tops of two mucosal folds
Grade B	One (or more) mucosal break >5 mm long that does not extend between the tops of two mucosal folds
Grade C	One (or more) mucosal break that is continuous between the tops of two or more mucosal folds, but that involves <75% of the circumference
Grade D	One (or more) mucosal break that involves at least 75% of the esophageal circumference

Reproduced from Lundell LR, Dent J, Bennett JR, et al. Endoscopic assessment of oesophagitis: clinical and functional correlates and further validation of the Los Angeles classification. *Gut*. 1999;45(2):172–180; with permission from BMJ Publishing Group Ltd.

Biopsy of the esophageal mucosa is performed during endoscopy, and tissue samples are evaluated by microscopy for evidence of Barrett metaplasia or neoplastic disease. In patients with suspected Barrett metaplasia, the biopsy is obtained after the esophagus has healed to prevent misinterpretation of the inflammatory markers for dysplastic syndrome. Mucosal biopsy for inflammatory markers in nonerosive disease remains debatable.

AMBULATORY ESOPHAGEAL REFLUX MONITORING

Ambulatory pH monitoring is indicated before endoscopic or surgical interventions in patients with NERD, in patients where a diagnosis of GERD is not clear, or in patients with persistent symptoms who have trialed twice-daily PPI therapy.[62,198] A small (2–3 mm diameter) pH electrode is threaded through the patient's nostril (similar to placing a nasogastric tube), past the patient's larynx, to ~5 cm above the LES in the distal esophagus.[168] Once it is connected to a logging device, which documents pH measurements every few seconds, it allows for the determination of reflux events (defined as esophageal pH <4), duration of reflux events, and percentage of time within a 24-hour

period that the patient's pH is <4. The patient is asked to keep a diary to record symptomatic events that can be correlated with a decrease in esophageal pH. This is especially important when correlating extraesophageal manifestations with reflux events.

RADIOLOGIC TESTING

Barium radiography is no longer recommended for GERD diagnosis.[62]

ESOPHAGEAL MANOMETRY

Esophageal manometry is used to evaluate the patient's LES pressure and esophageal peristalsis.[3] This procedure does not have a specific role in the diagnosis of GERD, because it does not detect the presence of acid within the esophagus. It is used primarily to evaluate patients before 24-hour continuous ambulatory pH monitoring and antireflux surgical procedures (eg, Nissen fundoplication) to determine the location of the LES.[3,199]

Case 23-4, Question 2: L.F.'s frequent severe symptoms continue despite OTC ranitidine 150 mg orally twice daily, and the presence of warning signs warranted that she undergo endoscopy, which revealed moderate esophagitis (Los Angeles grade C), the presence of an esophageal stricture, and no evidence of Barrett metaplasia. Esophageal dilation was performed during the procedure to widen the lumen of the esophagus. What treatment options exist for L.F.?

Pharmacotherapy

ANTACIDS

Antacids are useful only in the relief of mild symptoms associated with GERD (see section on Nonpharmacologic Measures and Self-Directed Treatment). Because of their short duration of action and inability to heal erosive esophagitis, they are not an option for treating moderate-to-severe GERD.[62,168]

HISTAMINE-2 Receptor Antagonists

H_2RAs are effective in treating patients with mild-to-moderate GERD, but response rates vary with the severity of disease, the dose of the drug, and the duration of therapy. H_2RAs are considered equally effective when used in equipotent doses for symptomatic relief and esophageal healing (**Table 23-1**). They are effective in reducing nocturnal symptoms, but only modestly effective in relieving meal-related symptoms because they only block one mechanism of parietal cell activation (the H_2 receptor).[168] H_2RAs relieve symptoms in about 50% to 60% of patients treated after 12 weeks of continuous therapy.[200] Increasing the H_2RA dose may not improve symptoms, but may lead to tachyphylaxis (tolerance). Esophageal healing requires higher doses (eg, famotidine 40 mg bid) compared with those used for symptom relief (**Table 23-1**). Esophageal healing rates with H_2RAs are reported to be about 50% after 8 to 12 weeks of treatment, but rates will vary depending on the degree of esophagitis.[200] For example, endoscopic healing rates in trials with high-dose H_2RAs were ~60% to 90% in patients with grades 1 and 2 esophagitis, but were only 30% to 50% in patients with more severe disease (grades 3 and 4 esophagitis).[168,200]

PROTON-PUMP INHIBITORS

PPIs are the drugs of choice for patients with frequent, moderate- to-severe GERD symptoms and esophagitis because they provide more rapid relief of symptoms and esophageal healing than do H_2RAs. When used in recommended doses, all of the PPIs provide similar rates of symptom relief and esophageal healing (see **Table 23-1**). Their superior efficacy when compared with H_2RAs is related to their ability to maintain an intragastric pH <4 for a longer duration time (up to 24 hours/day vs up to 10 hours with an H_2RA).[201] Typically, PPIs are taken once daily 30 to 60 minutes before breakfast, but if a second dose is required, it should be taken before the evening meal.

A large meta-analysis of 16 trials confirms that PPIs are superior to H_2RAs for achieving rapid and complete relief of GERD symptoms. Complete symptom relief (within 4–12 weeks) was achieved in 77.4% of patients taking a PPI versus 47.6% of those taking an H_2RA ($P < .0001$).[200] PPIs have also been shown to heal esophagitis more quickly and effectively than do H_2RAs. In the same meta-analysis, which evaluated 43 double-blinded or single-blinded, randomized studies (including patients with severe esophagitis), PPIs (83.6%) were more effective than were H_2RAs (51.9%) at healing erosive esophagitis at 12 weeks.[200] Healing also occurred more quickly with PPI therapy in that by the second week, 63.4% of patients had healed with the PPI, whereas it took 12 weeks with the H_2RAs for 60.2% of patients to heal.[200] Another large meta-analysis, which evaluated >33 randomized trials, demonstrated similar results, with 81.7% of patients healed at 8 weeks with a PPI versus 52.0% with an H_2RA.[31]

Esophageal healing among PPIs appears to be equivalent because about 85% to 90% of patients achieved complete healing at 8 weeks in numerous head-to-head trials with equivalent doses.[26–29] One meta-analysis, which compared esophageal healing rates among omeprazole 20 mg, lansoprazole 30 mg, pantoprazole 40 mg, and rabeprazole 20 mg (each given once daily), reported no statistically significant difference.[25] However, all of the PPIs were superior to ranitidine 300 to 600 mg/day. Esomeprazole 40 mg once daily has been reported to be superior to omeprazole 20 mg once daily, at both 4 and 8 weeks, when used to heal erosive esophagitis.[202] However, the esomeprazole 40 mg and omeprazole 20 mg doses are not equipotent, and this study has been heavily criticized based on this fact. Another study, which compared equipotent doses of esomeprazole (40 mg) and lansoprazole (30 mg), also suggests that esomeprazole has statistically significant greater healing rates (92.6% vs 88.8%, respectively, $P = .0001$).[28] In contrast, a similar study comparing lansoprazole 30 mg with esomeprazole 40 mg showed no statistical difference in esophageal healing, albeit with a smaller population.[29] Dexlansoprazole modified

release (MR) 60 mg once daily has been compared with lansoprazole 30 mg once daily in randomized, double-blind clinical trials to assess healing of erosive esophagitis.[203] The results using life-table analysis reveal similar healing rates with dexlansoprazole MR 60 mg and lansoprazole 30 mg (92%–93% vs 86%–92%, respectively), but the results were not statistically significant.[203] A higher dose of dexlansoprazole MR (90 mg daily) was superior to lansoprazole (30 mg daily) in patients with more severe disease, but these are not equipotent doses. In spite of the lack of supportive evidence, some clinicians prefer to use esomeprazole 40 mg/day or dexlansoprazole MR 60 mg/day for patients with severe erosive esophagitis.

The ability of a high-dose PPI to reverse Barrett metaplasia remains controversial.[168,204] Although studies have demonstrated islands of normal squamous epithelium returning, no data have determined that this is associated with a risk reduction in adenocarcinoma.[168,204] In fact, others have suggested that this return of normal mucosa may actually mask carcinogenic changes occurring deeper in the gastric mucosa.[205]

PROKINETIC AGENTS

Metoclopramide in addition to PPI therapy may be effective in the management of GERD by increasing LES pressure and stimulating the motility of the upper GI tract without altering gastric acid secretion.[168] Combination therapy of metoclopramide and an H_2RA was not shown to be effective.[206] Although prokinetic agents combined with a PPI may provide symptomatic relief, there is no clear role in the absence of gastroparesis, and they are associated with numerous side effects (eg, sedation, anxiety, extrapyramidal symptoms, etc.).[62,168]

PPIs are considered the drugs of choice for patients with frequent or severe GERD symptoms, or who have complicated disease, because of their potent inhibition of gastric acid secretion (**Fig. 23-5**).[62,169,191–193] In this case, L.F. presents with severe esophagitis and will require a once-daily PPI to relieve her symptoms and heal the

esophagus (Table 23-1). A reasonable option for L.F. would be lansoprazole 30 mg daily to be taken 30 to 60 minutes before breakfast each morning for the next 8 weeks; however, if the cost of therapy is an issue, generic omeprazole 40 mg daily would also be an acceptable alternative. L.F. should also be counseled regarding lifestyle and dietary modifications, including smoking cessation and abstinence from alcohol. She should avoid eating large meals before bedtime and may wish to elevate the head of her bed by 6 to 8 inches.

Maintenance Therapy

Case 23-4, Question 3: L.F.'s symptoms resolved in about 2 weeks after starting PPI therapy, and she remained asymptomatic after 8 weeks. She then underwent endoscopy again, which revealed that the esophagus had healed completely. Her primary care physician then stopped the PPI. Now, 2 weeks later, she is experiencing mild heartburn. Is L.F. a candidate for long-term maintenance therapy?

GERD is a chronic disease. Up to 80% of patients with severe esophagitis and 15% to 30% with less severe disease have a symptomatic relapse within 6 months of discontinuing treatment.[168] The goal of maintenance therapy is to keep the patient symptom free and prevent potentially life-threatening complications. Continuous maintenance therapy with a daily PPI is more effective than is an H_2RA, with reported relapse rates of 25% and 50%, respectively.[168] Thus, PPIs are the drugs of choice for maintaining remission in patients with healed esophagitis. An H_2RA may be considered for patients with mild nonerosive disease. Although half of the PPI dose used for esophageal healing has been suggested, guidelines indicate that the recommended maintenance dose should be the dose that is required to render the patient asymptomatic.[62,192] Maintenance therapy, to reduce the risk of morbidity associated with chronic, relapsing disease, should be initiated with lansoprazole 15 to 30 mg once daily or an equivalent PPI dose given the severity of

L.F.'s esophagitis and symptomatic recurrence after discontinuing the PPI.

On-Demand Pharmacotherapy

The use of intermittent (on-demand) courses of PPI therapy (2–4 weeks) has been suggested as being potentially beneficial in patients with GERD.[207–212] One trial, which compared continuous maintenance therapy with esomeprazole 20 mg daily versus on-demand therapy with the same drug and dose in patients with healed erosive esophagitis, reported that continuous therapy was superior to on-demand therapy (81% vs 58%, respectively) in maintaining endoscopic remission at 6 months.[212] The ability to maintain remission with on-demand therapy was reduced as the severity in esophagitis increased. Although numerous studies with a variety of PPIs have demonstrated patient satisfaction with on-demand therapy, a systemic review of 17 trials evaluating the use of on-demand therapy indicates that intermittent therapy should only be considered in patients with mild, nonerosive disease.[207–211]

Combination of a Proton-Pump Inhibitor and Histamine-2 Receptor Antagonists

The addition of an H_2RA at bedtime to a once- or twice-daily PPI regimen is sometimes used for patients who continue to have nocturnal symptoms, although the evidence to support this combination remains inconclusive and current guidelines do not endorse this type of antisecretory management strategy at this time.[62] The rationale for this practice is based on evidence that suggests a period of nocturnal acid breakthrough (defined as intragastric pH <4 for >1 hour during the night) in a significant number of patients despite twice-daily PPI therapy, suggesting that histamine release may have an important function in nocturnal acid secretion.[213] One study suggests that the addition of an H_2RA to a twice-daily PPI regimen resulted in a statistically significant reduction

in nocturnal acid breakthrough during the sleeping hours.[213] This trial, however, evaluated only a single bedtime dose of an H_2RA and did not consider the tachyphylaxis that can occur with continuous use. A subsequent trial using a twice-daily PPI regimen with continuous use of an H_2RA for 4 weeks demonstrated no difference in nocturnal acid suppression, suggesting that tolerance does play an important role in the use of H_2RAs for this indication.[14] It has been theorized that one way to possibly avoid this occurrence is to use the H_2RA on only an as-needed basis when lifestyle and dietary modifications are not effective for preventing nocturnal symptoms.[168]

Nonerosive Reflux Disease

Up to 75% patients with typical GERD symptoms who undergo endoscopy will not have evidence of esophagitis or complicated disease.[173] These patients are described as having functional heartburn, NERD, or ENRD, and often undergo 24-hour ambulatory pH monitoring to determine whether abnormal reflux is present despite a negative endoscopy finding. A trial of a PPI is usually indicated, despite no esophageal findings, because many patients will respond to this therapy.[173] Further medical evaluation is required if a patient does not respond to PPI therapy despite a doubling of the daily dose.

Extraesophageal Manifestations

CASE 23-5

Question 1: S.P. is a 71-year-old retired male who was eating dinner with his wife when he experienced a sudden onset of chest pain described as crushing, burning, and squeezing. His wife notified emergency personnel, who transported S.P. to the emergency department. His past medical history reveals some cardiovascular risk factors, including age, hypertension, hyperlipidemia, and a sedentary lifestyle. His medications before admission include aspirin 81 mg daily, hydrochlorothiazide 25 mg daily, and atorvastatin 40 mg at bedtime. He also takes OTC famotidine 20 mg daily as needed for dyspepsia. On

examination, he reports substernal crushing chest pain that has lasted >1 hour. He is diaphoretic and extremely anxious. He denies any shortness of breath, pain radiating to the upper extremities or jaw, or cough. His vital signs include a temperature of 99.1 °F (37.28 °C), blood pressure of 155/95 mm Hg, and heart rate of 115 beats/minute. Pertinent laboratory results at this time are as follows:

White blood cell (WBC) count, 7700/μL
Hgb, 14.2 g/dL
Hct, 45%
Platelets, 270,000/μL
SCr, 1.1 mg/dL
BUN, 11 mg/dL
Total cholesterol, 161 mg/dL
Low-density lipoprotein, 93 mg/dL
High-density lipoprotein, 30 mg/dL
Triglycerides, 190 mg/dL
Sodium, 141 mEq/L
Potassium, 4.1 mEq/L
Troponin I, 0.3 ng/mL

Electrocardiogram reveals sinus tachycardia with no evidence of ST-segment elevation, depression, or T-wave inversion or new left bundle branch block. Because of S.P.'s cardiovascular risk factors and indeterminate troponin, he underwent immediate diagnostic cardiac catheterization, which showed normal coronary angiography and an ejection fraction of 65%. S.P. was diagnosed with noncardiac chest pain (NCCP).

Could S.P.'s chest pain be associated with an extraesophageal manifestation of GERD?

Extraesophageal (atypical) manifestations of GERD are those signs and symptoms that occur outside of the esophagus, yet are presumed to be associated with GERD. The extraesophageal manifestations of GERD include NCCP; pulmonary symptoms; problems related to the ear, nose, and throat; as well as hypersalivation and dental erosions (**Table 23-10**). Interestingly, these symptoms are often the only problem that a patient has when he or she presents to the health care provider.[168,214]

Table 23-10
Atypical Manifestations of Gastroesophageal Reflux Disease

Noncardiac Chest Pain	Pulmonary

Noncardiac Chest Pain	Pulmonary
Ear, Nose, and Throat	Chronic cough
Laryngitis/pharyngitis	Nonallergic, nonseasonal asthma
Hoarseness	Aspiration
Globus sensation	Bronchiectasis/bronchitis
Laryngeal cancer	Sleep apnea
Sinusitis	Idiopathic pulmonary fibrosis
Otitis	Pneumonia
Other	
Hypersalivation	
Dental erosions

NONCARDIAC CHEST PAIN

About 30% of patients with angina-like chest pain have normal coronary arteries or minimal microvascular disease, as demonstrated by cardiac angiography.[215] Up to 60% of these patients will have concomitant GERD, as demonstrated by an abnormal esophageal endoscopy or ambulatory pH monitoring.[168,215] The symptoms associated with NCCP are very similar to those associated with cardiac angina. The chest pain is usually described as crushing, squeezing, or burning, retrosternal in location, and with or without lateral radiation to the upper extremities, back, neck, or jaw. The pain is often temporarily related to a meal or occurs nocturnally, usually awakening the patient and continuing for hours. An appropriate workup for coronary artery disease must be performed in all patients presenting with chest pain before considering a GI cause or trial of antireflux therapy.[62,215] This is especially important in females, the elderly, and patients with diabetes because their initial presentation may be similar to that of

GI symptoms when, in fact, an acute coronary syndrome is present. In patients with NCCP presenting with GERD symptoms, it is recommended to do diagnostic evaluation with endoscopy and ambulatory pH monitoring before an empiric PPI trial because data suggest no difference in this patient population in response to PPI versus placebo.[62,216]

ASTHMA AND GASTROESOPHAGEAL REFLUX DISEASE

Respiratory symptoms commonly associated with asthma such as cough, dyspnea, wheezing, and chest tightness are also seen in patients with GERD.[217] Reflux symptoms are common among patients with asthma, with reports ranging from 30% to 90%. One pathogenic theory is the vagal reflex theory, which proposes that symptoms result from the direct irritation of the vagus nerve when refluxate comes into contact with the esophageal mucosa, resulting in reflex bronchospasm.[218,219] In contrast, the microaspiration or reflux theory proposes that aspiration of refluxed acid into the lungs causes caustic injury of tissue within the bronchial tree, resulting in asthmatic symptoms.[219,220]

Although epidemiologic studies have suggested an association between GERD and asthma, a causal relationship remains to be established.[221] Significant controversy exists regarding the benefit of antireflux pharmacotherapy in patients with asthma, especially in those patients who do not endorse typical GERD symptoms. An important meta-analysis of trials that evaluated the effects of antireflux therapy on patients with asthma indicates that asthma symptoms improved in 69% of patients, that the use of asthma medications was reduced by 62%, and that only 26% of the subjects showed improvement in evening peak expiratory flow rate; all other pulmonary function tests showed little or no change with antireflux therapy.[222,223] However, this meta-analysis only evaluated studies of up to 8 weeks in duration. A large randomized, double-blind trial evaluated esomeprazole 40 mg twice daily versus placebo for 6 months in patients with poorly controlled asthma who were managed with inhaled corticosteroids and who lacked typical GERD

symptoms; results revealed no benefit in asthma control with the addition of a PPI, despite 40% of subjects demonstrating GERD by ambulatory reflux monitoring.[224] The American Gastroenterological Association guidelines accepts the use of an empiric trial of twice-daily PPI for patients with asthma and with typical GERD symptoms, but that reflux monitoring should be considered before PPI trial in patients with asthma and atypical GERD symptoms.[62]

OTOLARYNGOLOGY SYMPTOMS AND GASTROESOPHAGEAL REFLUX DISEASE

GERD is the most common etiologic factor in 60% of patients with chronic laryngitis and in 25% to 50% of patients with a globus sensation (the feeling that something is caught in the throat).[225] Symptoms relating to GERD are responsible for up to 10% of the patients seen by otolaryngologists.[225] The most likely mechanism for the pathophysiology of GERD-related laryngitis is that damage and inflammation occur at night while the patient is sleeping. It is during this time when upper esophageal sphincter pressures are especially low and the protective or neutralizing mechanisms of cough and salivation are suppressed.[226] This damage may be in addition to injury or laryngeal inflammation sustained from other causes, such as excessive voice usage, smoking, chronic throat clearing or cough, vomiting, or injury from endotracheal tubes.[214,227] The extent of injury in GERD-related hoarseness is directly related to the exposure time of the pharyngeal mucosa to the refluxate as well as the pH. Patients with GERD- related hoarseness usually do not have any other GERD-related symptoms.[214] The diagnostic procedure of choice is laryngoscopy, and should be considered in all patients presenting with GERD-related hoarseness. Once the diagnosis of GERD-related hoarseness or laryngitis is established, the patient will likely require extended high-dose PPI therapy, with the understanding that the majority of patients will relapse within 6 weeks once therapy is discontinued.[228]

TREATMENT FOR THE EXTRAESOPHAGEAL MANIFESTATIONS OF GASTROESOPHAGEAL REFLUX DISEASE

Experts suggest that treatment should be initiated with a high-dose (twice-daily) PPI, but if there is no response in 2 to 3 months, then the patients should be evaluated and managed as having refractory GERD.[62]

S.P.'s chest pain is not of cardiac origin based on angiographic findings. Therefore, it is reasonable to presume that he is having an extraesophageal manifestation of GERD. S.P.'s symptoms were meal related, and he has a history of dyspepsia for which he takes an OTC H_2RA. The H_2RA should be discontinued, and S.P. should be given a trial of empiric twice-daily PPI therapy for a period of 2 to 4 weeks. If symptoms are severe, the use of endoscopy (to determine whether esophageal damage is present) or 24-hour esophageal pH monitoring (to correlate reflux events with symptomatic chest pain) is appropriate.

Antireflux Surgery

Case 23-5, Question 2: S.P. responded well to the trial of omeprazole 40 mg orally twice daily and has not had chest pain in 2 months. He has heard that surgical options that may eliminate his need for medications exist, because they are very expensive for him. Is S.P. a candidate for antireflux surgery?

Numerous surgical and endoscopic procedures exist for patients with GERD, but they vary by efficacy, adverse effects, and long-term durability. Examples include laparoscopic Nissen fundoplication, laparoscopic Hill gastropexy, transoral incisionless fundoplication, and magnetic sphincter augmentation. Obese patients being evaluated for GERD surgical intervention should be considered for bariatric surgery.[3] The primary goal of these procedures is to restore LES pressure by repairing a hiatal hernia or diaphragmatic hiatus. Appropriate candidates include patients who are in good health and request another treatment option as a result of poor medication adherence, patients who are unable to afford their medication,

patients who suffer from side effects or worry about risks with long-term therapy, patients with extraesophageal symptoms who have responded well to antireflux therapy, or patients experiencing volume regurgitation and aspiration of gastric contents who have not responded to PPI therapy.[62,163,168,199] Despite the availability of these surgical options, the consideration of antireflux surgery is one in which the benefits should be heavily weighed against the risks of such an invasive approach because these procedures are not without potential complications. The effectiveness of these procedures has been questioned, because many patients will still require drug therapy.[62,168] S.P. has responded well to high-dose PPI therapy for his NCCP, but he describes some financial difficulties with affording his medications. In addition, he is 64 years old, which may increase the risk associated with surgery. S.P. should be referred for further medical evaluation to determine whether he is a candidate for antireflux surgery.

UPPER GASTROINTESTINAL BLEEDING

Upper GI bleeding is a common medical emergency that occurs in up to 160 cases per 100,000 adults annually, and is associated with increased morbidity and mortality as well as substantial costs to the health care system.[229,230] Despite advances in endoscopic hemostatic therapy and pharmacotherapy, the mortality rate associated with upper GI bleeding remains at 5% to 15%, which is the same as it has been for the past 20 to 40 years.[229–232] Upper GI bleeding can be categorized as either variceal or nonvariceal bleeding. Variceal bleeding is caused by esophageal or gastric varices, and is discussed in a separate chapter (see Chapter 25, Complications of End-Stage Liver Disease). Nonvariceal bleeding most commonly describes bleeding associated with peptic ulcers (including stress ulcers), mucosal erosions (esophagitis, gastritis, duodenitis), or Mallory–Weiss tears (a tear near the gastroesophageal junction associated with retching or coughing);

other causes include malignancy and malformation.[114] The term *stress ulcer* offers a simplified nomenclature for the more apt description of stress-related mucosal bleeding (SRMB); although peptic ulcer bleeding and SRMB generally stem from acid-related disorders, their pathophysiology, presentation, risk assessment, and clinical management differ.[233–235]

Peptic Ulcer Bleeding

EPIDEMIOLOGY

The majority of upper, nonvariceal GI bleeding is caused by PUD.[114,229,230,232] Bleeding ulcers account for >400,000 hospitalizations in the United States each year.[230] As mentioned, the mortality rate for peptic ulcer bleeding can be as high as 15%. It has been suggested that an older presenting patient population (>60 years of age) with a greater number of comorbidities may account for this continued high mortality rate.[229–231] Fortunately, the vast majority (80%) of upper GI bleeding events are self-limited and require only minimal intervention.[231] National data derived from a U.S. database demonstrate a decreasing mortality rate (3.54%) in elderly patients with complications during 2001 to 2009.[236] Length of stay has been dramatically reduced in the majority of patients who receive early endoscopy (within 24 hours of admission).[229,230] However, in the 20% to 25% of patients who continue to bleed or rebleed after appropriate intervention, mortality increases to nearly 40%.[114,237]

PATHOPHYSIOLOGY

The most common causes of upper GI bleeding in patients with PUD are NSAID use and *H. pylori* infection.[93] Bleeding occurs when an ulcer extends deeper into the mucosa and erodes the wall of a blood vessel.[238] The incidence of *H. pylori* infection in bleeding ulcers is 15% to 20% lower than in patients with nonbleeding ulcers.[238] Bleeding associated with PUD is generally not caused by the hypersecretion of gastric acid, with the exception of patients with ZES.[238] The pathophysiology and risk factors associated with PUD

are described earlier in this chapter (see section on Peptic Ulcer Disease).

CLINICAL ASSESSMENT AND DIAGNOSIS

The clinical presentation of a patient with a bleeding peptic ulcer usually includes the presence of melena (dark, tarry stools), which occurs in 20% of patients, hematemesis (vomiting of blood) in 30%, and both in ~50% of patients. Up to 5% of patients present with hematochezia (bloody diarrhea) indicative of rapid and substantial blood loss.[238] The primary step in evaluating the patient is to assess hemodynamic status and the degree of urgency for rapid medical management.[238,239] Two validated prognostic scales exist for early risk stratification into high-risk or low-risk adverse outcomes for patients presenting with upper GI bleeding: the pre-endoscopic Rockall score and the Glasgow– Blatchford score.[239] The pre-endoscopic Rockall score only uses clinical patient data at presentation (eg, blood pressure, pulse, age, comorbidities), whereas the Blatchford score utilizes both laboratory (eg, Hgb, BUN) and clinical patient data (typically available early after admission); both are used to determine which patients are at higher risk for further bleeding or death, and also may assist in determining the need for and emergent nature of endoscopy, time of discharge, and level of care in the individual patient.[114,229,230,239] After endoscopy, the complete Rockall score incorporates endoscopic data to predict the likelihood of rebleeding and mortality.[114,229,230] Hypovolemia owing to substantial blood loss can rapidly lead to shock. The initial management of these patients should focus on volume resuscitation and improving the patient's hemodynamic status. Clinical features suggestive of high risk for rebleeding or mortality include patients older than 65 years, serious comorbidities (eg, hepatic or renal dysfunction, cardiac or pulmonary disease), hemodynamic instability (eg, hypotension, tachycardia), shock, poor health, continued bleeding, mental status changes, and prolonged prothrombin/activated partial thromboplastin time (aPTT) (or elevated international normalized ratio [INR]).[114,229,231,237,238,240,241]

These patients should immediately be transferred to an intensive care setting.

Most patients should receive early diagnostic endoscopic evaluation within 24 hours of presentation to determine the source of the bleeding, to predict the risk for rebleeding, and, when required, to perform endoscopic interventions directed at stopping the bleeding ulcer and restoring hemostasis.[229,230] Risk of rebleeding may be predicted based on the presenting lesion(s) identified on endoscopy.[114,238] The most common ulcer identified on endoscopy is a clean-base ulcer found in ~42% of patients. This ulcer has a very low risk of rebleeding (5%), and the patient can usually be discharged immediately after recovery from the endoscopy and managed with appropriate oral antisecretory therapy.[229,239] Intermediate stigmata of bleeding include lesions identified as flat-spot ulcers and/or adherent clots, which have a risk of rebleeding of 10% and 22%, respectively. Although endoscopic procedures are not usually necessary with flat-spot ulcers, adherent clots remain an area of controversy and usually require the endoscopist to attempt to remove the clot and manage the underlying lesion.[229] Patients identified with high-risk ulceration (nonbleeding visible vessel or active bleeding) will require endoscopic intervention and have a high risk of rebleeding (43% and 55%, respectively) despite intervention. Nonbleeding visible vessel and active bleeding are associated with an 11% mortality on initial presentation.[238] Ulcer size is also predictive of mortality and rebleeding, because ulcers >1 or 2 cm in diameter confer greater risk.[238] Despite appropriate endoscopic hemostasis, ~20% of patients with peptic ulcer bleeding will rebleed within 48 to 72 hours of treatment.[114,229,237,238] Mortality associated with rebleeding is ~30% to 37%.[237] Patients undergoing endoscopy should be tested for *H. pylori* infection with biopsy (rapid urease test), because infection with this organism is associated with an increased risk of rebleeding.[229,230] Because false negatives can occur in the presence of active bleeding, all patients who are *H. pylori* positive should have a confirmatory follow-up test with serologic antibody testing on discharge to ensure that the patient is not infected.[229]

TREATMENT

Patients with upper GI bleeding require rapid risk stratification based on the presenting signs and symptoms. Patients with hemodynamic instability require immediate institution of resuscitative measures.[114,229,230,239,242] IV access should be obtained with two large-bore (eg, 16–18 gauge) catheters to facilitate the administration of fluids and blood products.[114,230] Intravascular volume should initially be replenished with normal saline to prevent the patient progressing into hypovolemic shock. During this time, blood can be typed and crossed in the event a transfusion is required. Guidelines recommend the transfusion of packed red blood cells for patients with an Hgb level of <7 g/dL; however, consideration is warranted in the patient with tachycardia or hypotension and an Hgb level of 10 g/dL.[229,230] Although not required, a nasogastric tube may be placed to allow for lavage and determination of the upper GI tract as the source of the bleed and evaluation of continued bleeding.[114,229,230,239,242]

Endoscopic evaluation with hemostatic techniques (when required) should be performed as soon as safely possible.[229,230] Endoscopic hemostasis is the cornerstone of management of patients with serious bleeding ulcers, because it reduces the incidence of rebleeding, the need for surgery, and mortality when compared with placebo or drug therapy.[229,230] Endoscopic procedures include thermocoagulation, laser therapy, injection therapy (epinephrine, ethanol, or saline), injection with sclerosing agent, or placement of endoscopic clips.[229,239] Despite initial hemostasis, however, the potential for rebleeding remains high, especially in patients with high-risk lesions.[114,229,230,236–239]

Improvements in hemostatic parameters (eg, platelet aggregation, inactivation of pepsin, and correction of coagulation) leading to clot stabilization correlate directly with an intragastric pH >6. Therefore, treatment with an antisecretory drug is beneficial in patients after endoscopy to promote healing of the lesion.[230,236,239,240] After the acute phase, the patient should be placed on appropriate drug therapy to continue healing and prevent ulcer recurrence (see

section on Peptic Ulcer Disease). Patients who are *H. pylori* positive should receive appropriate eradication pharmacotherapy and confirmation of eradication at a later time.[229,239]

Histamine-2 receptor antagonists

Once widely used to manage upper GI bleeding, H_2RAs are now considered inferior to PPIs for reducing the incidence of rebleeding and the need for surgery.[229,230] This is likely related to the inability of H_2RAs to achieve an intragastric pH ≥6 (even with continuous IV administration) and the rapid development of tachyphylaxis (especially with high IV doses).[17,229,240] Thus, H_2RAs are no longer recommended for the prevention of rebleeding associated with a peptic ulcer.[229,230,239]

Proton-pump inhibitors

PPIs are the drugs of choice to reduce recurrence of upper GI bleeding ulcers and the need for surgical intervention.[114,229,230,239,243–245] However, no clinical trials were able to show a mortality benefit with PPIs when entire treatment cohorts were evaluated.[243–245] Two meta-analyses performed by the Cochrane Collaborative group evaluating PPIs administered IV or orally against H2RAs or placebo showed a reduction in rebleeding, surgery, and repeat endoscopic treatment.[243,244] Based on these available data, PPI therapy for peptic ulcer bleeding is superior to H_2RAs and placebo.[230] Although no reduction in the number of deaths were identified when all patients were considered, PPI treatment of patients at the highest risk of mortality, as evidenced by endoscopically determined active bleeding or nonbleeding visible vessel, did impart a mortality benefit.[244] All-cause mortality was also reduced in Asian trials, with a concomitant greater reduction in the incidence of rebleeding and need for surgery than in trials performed elsewhere in the world. This may be explained by the inclusion of a younger patient population, more potent acid suppression because of genetic polymorphism in

CYP450 metabolism leading to a slower clearance of PPIs, a lower parietal cell mass, and a greater incidence of *H. pylori* infection.[243]

Despite the data, important questions remain as to the most appropriate dose and route of administration for PPIs in patients with peptic ulcer bleeding. A pre-endoscopic PPI bolus plus continuous infusion has been shown to reduce the proportion of patients with active bleeding at endoscopy, reduce the requirements for endoscopy, and reduce hospital stay.[239,246] However, this strategy should not replace early endoscopic management in high-risk patients, because combination PPI therapy with endoscopic maneuvers has been proved to be more effective than is monotherapy with an IV PPI.[229,230,247] Evidence suggests that most patients with low-to-intermediate risk lesions (clean-base or flat-spot ulcers) and who are hemodynamically stable may be treated with a once-daily oral PPI and immediately discharged after endoscopy, because rebleeding is infrequent in this population.[229,239,243,248]

After successful endoscopic hemostasis, patients with adherent clots and high-risk bleeding ulcers (active bleeding and nonbleeding visible vessels) are typically managed with high-dose IV bolus and continuous IV infusion of a PPI (omeprazole 80 mg or equivalent PPI followed by 8 mg/hour for 72 hours).[229,239] Some patients may be switched to an oral PPI if rapid stabilization occurs, but careful clinical assessment should be performed to ensure the patient is stable.[248] Of note, a recent meta-analysis has called into question the need for high-dose, continuous PPI therapy, suggesting that intermittent PPI therapy may be noninferior.[249] Further, another meta-analysis has suggested that PPI therapy is associated with reduced blood transfusion requirements.[250] To more effectively assess the validity of the findings from these meta-analyses, a carefully designed prospective randomized controlled trial would need to take place.

Once the high-risk patient has stabilized and is considered safe for discharge after endoscopy and 72 hours of IV PPI, the patient should be discharged with a prescription for at least once-daily PPI pharmacotherapy for continued healing of the lesion and further prevention of rebleeding.[229,239] The actual dose and duration,

however, should be decided based on the patient's severity of disease and identified complications, with more severe disease warranting consideration of twice-daily therapy.[229,239] Patients with *H. pylori*–associated bleeding ulcers should receive standard therapy for eradication, although maintenance PPI therapy is not necessary unless the patient also requires NSAIDs or antithrombotics.[229,239] Patients who are required to remain on long-term NSAID therapy require long-term secondary prophylaxis with daily oral PPI therapy in an attempt to prevent future upper GI bleeding events; patients should consider a more COX-2–selective NSAID at the lowest effective dose plus daily PPI for this situation (see section on Nonsteroidal Anti-inflammatory Drug–Induced Peptic Ulcer).[229,239] When considering the role of cardioprotective aspirin in patients with previous ulcer bleeding, risks often outweigh benefits in primary prevention and benefits often outweigh risks in secondary prevention.[148] As such, aspirin therapy should only be restarted if the risk of cardiovascular complication outweighs the bleeding risk and only in combination with daily PPI therapy (the same concept applies to dual antiplatelet and anticoagulation therapy); for secondary prevention, aspirin should be resumed with daily PPI therapy as soon as possible after bleeding cessation (ideally 1–3 days but no more than 7 days).[229,239]

Other agents

Despite being commonly used in the management of variceal bleeding (see Chapter 25, Complications of End-Stage Liver Disease), the use of somatostatin or octreotide is not recommended for the management of nonvariceal upper GI bleeding because of insufficient supporting evidence.[229,230]

Stress-Related Mucosal Bleeding

Acute SRMB is a type of erosive gastritis that occurs in critically ill patients with severe physiologic stress (eg, surgery, trauma, organ failure, sepsis, severe burns, and neurologic injuries).[244,251–254] The

term *stress ulcer* is a misnomer in that SRMB may range from numerous diffuse superficial erosive mucosal lesions (those that do not penetrate the muscularis mucosa) to major deep ulceration (penetration of the muscularis mucosa and potentially submucosa).[233,234] Initial lesions occur early (<24 hours) and appear as subepithelial petechiae that can develop into superficial erosions and ulcerations.[234,254] Early stress-related mucosal lesions are multiple, usually asymptomatic, without perforation, and commonly bleed from superficial mucosal capillaries.[233,253] The gastric fundus is the most likely anatomic region of the stomach to be involved. Distal lesions involving the gastric antrum and duodenum have also been described, but tend to appear later in the hospital course and are often deeper and associated with a greater probability for bleeding.[233] SRMB from these lesions may be categorized into three distinct types based on clinical presentation.[233–235,253,254] Occult (hidden) bleeding is defined as aspirated gastric fluid or stool that is guaiac positive for the presence of occult blood and without other signs or symptoms.[235] Overt bleeding is defined as frank hemorrhage identified by hematemesis (bloody vomitus or the appearance of coffee grounds in gastric aspirates or vomitus), hematochezia (bloody diarrhea), or melenic stools.[235] Clinically important bleeding or life-threatening bleeding is the presence of overt bleeding that is associated with hemodynamic changes (tachycardia, hypotension, orthostatic changes, or Hgb concentration decline of >2 g/dL) and the requirement of transfusion of blood products.[235] Endoscopic therapy is generally not a viable option because of the extensive distribution of lesions associated with SRMB.[251]

EPIDEMIOLOGY

The majority (>75%) of the critically ill patients admitted to intensive care units (ICUs) will exhibit mucosal lesions consistent with SRMB within 24 hours of admission.[233–235,251,253,254] Only a small percentage (up to 6%) of these patients will progress to clinically important GI bleeding.[233–235,253,254] Clinically important SRMB has been associated with an increased length of stay in the ICU by up to 11 days, and

results in substantial increases in the cost of health care.[233,235,251,253,254] The mortality of clinically important SRMB approaches 50%, but mortality may also be associated with underlying comorbidities related to the critical illness.[244,254]

PATHOPHYSIOLOGY

Numerous factors have been identified in the pathogenesis of SRMB and resultant bleeding. These include gastric acid and pepsin secretion, disruptions to the normal homeostatic mechanisms that protect the gastric mucosa against the highly acidic environment (decreases in prostaglandin, bicarbonate, and GI mucous formation as well as impaired turnover of gastric epithelium), GI motility disturbances, and mucosal ischemia resulting from decreased blood flow.[234,235,251,253,254] Gastric acid and disruption of the mucosal barrier seem to be central factors associated with development of SRMB.[233,235,251] Because of the absence of protective defenses, substantial amounts of acid are not required for the formation of lesions, but some acid is required for damage to occur.[234] Although some patients may have increased acid secretion (eg, sepsis, CNS injuries, small bowel resections), the majority of critically ill patients have normal or decreased acid secretion.[233–235,252] Pepsin secretion is associated with the lysis of clots owing to its proteolytic action on fibrin.[251,255] Gastric prostaglandins play a key role in the cellular defense against gastric acid.[251] These prostaglandins are responsible for maintaining the integrity of the mucosal barrier by stimulating mucous and bicarbonate production, regulating blood flow, and, to some degree, inhibition of acid production. Mucosal ischemia secondary to splanchnic hypoperfusion also plays a large role in the pathogenesis of SRMB.[234,251,253] Mucosal ischemia is associated with reduced ability to neutralize hydrogen ions, leading to intracellular acidosis within the mucosa and subsequent cell death. These factors all contribute to an imbalance by increasing injurious factors and reducing the protective mechanisms within the gastric fundus.

RISK FACTORS

CASE 23-6

QUESTION 1: J.S., a 58-year-old, 242.51-pound (110-kg) male was admitted to the medical ICU for severe necrotizing pancreatitis identified on abdominal computed tomography. The patient was immediately made "nothing by mouth" (NPO) and started on imipenem/cilastatin 1000 mg intravenous piggyback (IVPB) every 6 hours. He was given hydromorphone 1 mg IV every 3 hours as needed for pain. He subsequently exhibited shortness of breath on his third day after admission, required intubation, and was placed on a ventilator. A chest x-ray showed a left lower lobe infiltrate suggestive of hospital-acquired pneumonia. Antibiotic coverage was increased with the addition of ciprofloxacin 400 mg IVPB every 8 hours and linezolid 600 mg IV every 12 hours. He has a temperature of 103.5 °F (39.72 °C), heart rate of 115 beats/minute, and blood pressure of 70/40 mm Hg. Pertinent laboratory results at this time include the following:

WBC count, 38,000/μL
Hgb, 13.6 g/dL
Hct, 40%
Platelets, 150,000/μL
SCr, 1.3 mg/dL
BUN, 24 mg/dL
INR, 1.0
aPTT, 39 seconds
Aspartate aminotransferase (AST), 292 units/L
Alanine aminotransferase (ALT), 305 units/L
Amylase, 508 units/L
Lipase, 624 units/L

In addition to the antimicrobials and initiation of fluid resuscitation, the critical care team is considering stress ulcer prophylaxis.

What risk factors does J.S. have (if any) for SRMB, and is he a candidate for stress ulcer prophylaxis?

Numerous risk factors have been associated with SRMB (**Table 23-11**).[233,235,251–254] However, a large landmark, multicenter, prospective study involving >2200 critically ill patients admitted to a medical ICU identified only the requirement of mechanical ventilation (respiratory failure) or coagulopathy as independent risk factors for development of clinically important bleeding.[239] Considering the cost

associated with the reduction of risk related to SRMB, the authors concluded that only these two risk factors warrant the use of prophylactic therapy. Because not all risk factors impose the same level of risk, clinical guidelines and most practitioners recommend prophylaxis only when the patient is mechanically ventilated, has a coagulopathy, or when two or more of the remaining risk factors are present (**Table 23-11**).[235,251,252,254,256,257] J.S.'s risk factors include septic shock as evidenced by hemodynamic instability and mechanical ventilation. Therefore, a prophylactic regimen to reduce the risk of SRMB is appropriate.

Table 23-11

Risk Factors for Stress-Related Mucosal Bleeding

Mechanical ventilation
Coagulopathy
Respiratory failure
Hepatic failure
Acute renal failure
Renal replacement therapy
Head/brain injury
Hypotension
Sepsis
Shock
Enteral feeding
High-dose corticosteroids[a]
Organ transplant
Anticoagulants
Severe burns (>35% of body surface area)
Intensive care unit stay >7 days
History of previous GI hemorrhage

GI, gastrointestinal.

[a]Greater than 250 mg/day hydrocortisone or equivalent.

TREATMENT

CASE 23-6, QUESTION 2: What options exist to prevent SRMB in J.S.?

Not all patients admitted to the ICU will require prophylaxis for SRMB. However, because mortality can be high in patients when bleeding occurs, evaluation of risk is of absolute importance to ensure that protective pharmacotherapy is initiated in appropriate patients.[233–235,251–254,256,257] Because acid is required for mucosal injury, the inhibition of gastric acid is the primary target when pharmacotherapy is used to reduce the risk of SRMB. An intragastric pH >4 is the recommended goal of therapy.[233,234,244,251–254] Therapeutic options include the use of antacids, sucralfate, H_2RAs, and PPIs (**Table 23-12**). When determining whether medication therapy is warranted, risk of pneumonia must also be assessed.[235,257] Beyond medications, enteral nutrition may provide protection against bleeding while increasing gastric pH to a similar or even greater extent than does acid suppression.[235,256] Within 48 hours of ICU admission, initiation of enteral nutrition has been evaluated as a means of prophylaxis against SRMB.[258] A meta-analysis of 17 studies suggested that patients who require enteral tube feedings may not require additional forms of SRMB prophylaxis and may also have a reduced risk of pneumonia or death when compared with patients receiving an H_2RA-based SRMB prophylaxis regimen.[258] This meta-analysis, however, was only hypothesis generating and should be interpreted with care until a large controlled study is available to confirm these findings.

Table 23-12
Stress-Related Mucosal Bleeding Prevention: Regimens and

Doses

Agent	Dose and Frequency of Administration	FDA Approval[a]
Antacid	30 mL PO/NG every 1–2 hours	No
Cimetidine	300 mg IV loading dose, then 50 mg/hour continuous IV infusion[b]	Yes
Famotidine	20 mg IV every 12 hours *or*	No
	1.7 mg/hour continuous infusion	No
Ranitidine	50 mg IV every 6–8 hours *or*	No
	6.25 mg/hour continuous infusion	No
Sucralfate	1 g PO/NG every 6 hours	No
Omeprazole	20–40 mg PO/NG[c] every 12–24 hours	No
Omeprazole/sodium bicarbonate powder for oral suspension	40 mg PO/NG initially, followed by 40 mg 6–8 hours later, then 40 mg PO/NG every 24 hours	Yes
Lansoprazole	30 mg PO/NG[c,d] every 12–24 hours	No
Pantoprazole	40 mg IV/PO/NG[c] every12–24 hours	No
Esomeprazole	40 mg IV/PO/NG every 12–24 hours	No

IV, intravenous; NG, nasogastric; PO, by mouth.

[a]For prevention of stress-related mucosal bleeding.

[b]Not available in the United States.

[c]Extemporaneously compounded in sodium bicarbonate.

[d]Oral disintegrating tablet.

Antacids

The use of aggressive antacid therapy is superior to placebo in reducing clinically important SRMB when an intragastric pH >3.5 is maintained.[251,253,254] Although antacids are effective in preventing SRMB, their use has fallen out of favor because of difficult administration regimens (every 1–2 hours) along with the continuous requirement of intragastric pH monitoring for dose titration, electrolyte abnormalities (especially in patients with renal dysfunction), diarrhea, constipation, and the potential risk of

aspiration pneumonia.[233,251,253,254] These issues, coupled with the fact that potent acid suppression is available in far more convenient dosage forms, have all but eliminated the use of antacids as SRMB prophylaxis.[251]

Sucralfate

Despite the fact that antisecretory therapy is preferred, sucralfate remains an available therapeutic option. Sucralfate is effective in preventing SRMB, but does not have an important effect on intragastric pH.[259,260] Early studies suggested a reduction in nosocomial pneumonia with sucralfate when compared with ranitidine or antacids; however, a subsequent randomized trial involving 1200 mechanically ventilated patients revealed no increase in pneumonia with H_2RAs when compared with sucralfate or antacids.[259–261] The usual dose of 1 g four times daily can present problems within the critical care setting because of multiple daily dosing, binding of other enterally administered drugs, and occlusion of nasogastric tubes (may be reduced with suspension formulation). Other potential issues include the risk of aluminum toxicity in patients with renal failure, constipation, and electrolyte imbalances. The concomitant use of sucralfate with antisecretory therapy may reduce the effectiveness of sucralfate because an intragastric pH <4 is needed for conversion to its active form, which binds to the gastric mucosa.[254]

Histamine-2 receptor antagonists

H_2RAs are effective in preventing SRMB; although previously the most widely used for this indication, PPIs now predominate.[235,256,257,262,263] Although only cimetidine continuous infusion has been FDA labeled for the prevention of SRMB, continuous or intermittent infusions of ranitidine and famotidine are preferred because of the adverse effect and drug interaction profile of cimetidine.[240,251,253] Continuous infusions have been suggested as being more effective than are intermittent infusions in maintaining a

pH >4, but there are no data comparing these two treatment options with respect to clinical outcomes.[233,251] Despite this, intermittent dosing of H_2RAs is used more commonly than are continuous infusions for the prophylaxis of SRMB.[240,253,262,263]

Numerous trials and meta-analyses have evaluated the effectiveness of H_2RAs for prophylaxis of SRMB.[235,264,265] Cook et al reviewed 63 randomized trials and determined that prophylaxis with H_2RAs was associated with a statistically significant reduction in overt and clinically important upper GI bleeding when compared with no therapy and a significant reduction in overt bleeding when compared with antacids.[264] A trend toward reduced clinically important bleeding was identified when H_2RAs were compared with sucralfate, but this was not statistically significant. In another meta-analysis, ranitidine was shown to be of no benefit in preventing SRMB while increasing the risk of pneumonia.[265] However, neither of these meta-analyses included the large study involving 1200 mechanically ventilated patients that compared sucralfate, ranitidine, and placebo.[261] Despite these conflicting results, H_2RAs remain an option, and are still sometimes used for the prophylaxis of SRMB.[262,263] One shortcoming of H_2RAs is that tolerance may develop (within 72 hours), which may theoretically lead to prophylaxis failure.[17]

Proton-pump inhibitors

PPIs, because of their profound ability to inhibit gastric acid secretion and the lack of tolerance to their antisecretory effect, have emerged as the preferred option for preventing SRMB. However, there is very little evidence to confirm their clinical superiority to H_2RAs for this indication. Numerous studies have compared PPIs with H_2RAs or placebo in critically ill patients in small populations using varied predetermined end points.[254,266] These studies suggest that PPIs provide greater acid suppression compared with H_2RAs and are likely to be as effective in preventing SRMB.[254,266] Alternative administration options exist for patients in the critical care setting

who cannot take medications by mouth, have nasogastric tubes in place, or have difficulty swallowing[254,267] (**Table 23-13**). One study in 359 critically ill patients evaluated the use of immediate-release omeprazole suspension in bicarbonate given via nasogastric tube versus IV cimetidine; results suggested that the PPI-bicarbonate suspension was associated with a greater mean time of intragastric pH >4 than was the cimetidine infusion, but that the rate of clinically important bleeding did not significantly differ between treatment arms.[268] Further, an extremely important analysis aimed at identifying the most appropriate dose for IV PPIs in SRMB prophylaxis was performed in >200 critically ill patients.[269] This analysis included five different dosing approaches of IV pantoprazole intermittent infusions (40 mg given every 8, 12, or 24 hours or 80 mg given every 12 or 24 hours) compared with cimetidine given as a 300-mg IV bolus immediately followed by a 50 mg/hour continuous infusion. The patients received a minimum of 48 hours of therapy with a maximum of 7 days. In all the study arms, pH control was achieved (defined as intragastric pH ≥4); however, in all the pantoprazole arms, pH control continued to improve from day 1 to 2, whereas a decline was noted in the cimetidine group, suggesting the occurrence of tachyphylaxis. No upper GI bleeding was noted in any patient during the trial regardless of treatment group assigned. The conclusions of this study demonstrated that patients may have adequate pH control with an initial IV dose of pantoprazole 80 mg followed by 40 mg IV every 12 hours.[269] A 2013 meta-analysis that included 14 studies totaling ~1700 patients evaluating the efficacy and safety of PPIs compared with H_2RAs demonstrated a statistically significant difference between the two options (favoring PPIs) with respect to the important end points of overt or clinically important bleeding; there were no differences with regard to mortality or incidence of pneumonia.[266] The incidence of nosocomial pneumonia in patients receiving PPI therapy for SRMB prophylaxis undergoing cardiothoracic surgery has been evaluated in two retrospective cohort studies.[267,270] Both studies demonstrated that patients receiving PPIs were at an

increased risk for developing pneumonia even after data adjustments for various risk factors.

Table 23-13

Alternative Proton-Pump Inhibitor Administration Options

	Omeprazole	Lansoprazole	Pantoprazole	Esomeprazole	Rabeprazole	Dexlansoprazole
Capsule granules sprinkled on selected soft foods (ie, applesauce)		✓[a]		✓[a]	✓[a]	✓[a]
Capsule granules mixed in water and flushed down NG tube				✓		✓[a]
Capsule granules mixed in juice (can be administered via NG tube if required)	✓[a]	✓[a]		✓[a]	✓[a]	✓[a]
Extemporaneous compound of PPI in bicarbonate for NG tube	✓	✓	✓			
Package for oral suspension	✓[a,b]	✓[a,c]		✓[a]		
Oral disintegrating tablet		✓[a]				
IV formulation	Not available in the United States	Removed from U.S. market	✓[a]	✓[a]		

IV, intravenous; NG, nasogastric; PPI, proton-pump inhibitor.

[a]Labeled by the U.S. Food and Drug Administration (FDA) for this administration option.

[b]Omeprazole suspensions available in 20- and 40-mg packets with bicarbonate (1680 mg); both contain same amount of bicarbonate, and two 20-mg packets cannot be substituted for one 40-mg packet.

[c]Not to be administered via nasogastric (NG) tube, because occlusion of tube is possible.

Type of stress ulcer prophylaxis and risk of nosocomial pneumonia in cardiac surgical patients: cohort study. *BMJ*. 2013;347:f5416.

More recently, a large randomized controlled trial compared pantoprazole to placebo in adult patients at risk for GI bleeding in the ICU; 90-day mortality and the number of clinically important events (GI bleeding, pneumonia, CDI, or myocardial ischemia) were similar in both arms.[256] This important trial further puts into question the

benefits and risks of widespread use of acid suppression therapy for SRMB prophylaxis. Although PPIs have become predominantly first-line therapy for the prevention of SRMB, additional studies are needed to confirm the most effective dose and route of administration to obtain optimal clinical outcomes in patients at risk for SRMB.[253,262] Recent data has prompted reevaluation of system-wide approaches to SRMB prevention and management; evidence also supports a broad and significant impact of pharmacist-led management programs for SRMB prophylaxis to reduce inappropriate prescribing/use of acid suppression therapy.[235,256,257]

MONITORING

CASE 23-6, QUESTION 3: J.S. has been started on famotidine 20 mg IV every 12 hours. How should this pharmacotherapy be monitored for safety and efficacy?

The famotidine dose should be adjusted to maintain an intragastric pH >4 and should be based on severity of the patient's illness, renal function, and intragastric pH measurements. The intragastric pH can be determined with an indwelling probe or by measuring the pH of nasogastric aspirates. The patient should be monitored for signs of bleeding (eg, presence of blood or coffee-ground material in nasogastric aspirates, hematemesis, hematochezia, or melena), hypotension, reductions in Hgb or Hct, and thrombocytopenia.

CASE 23-6, QUESTION 4: During the next 6 days, J.S. improves and is subsequently removed from mechanical ventilation and transferred to the medical ward. He is now able to eat normally. Should J.S. be continued on SRMB prophylaxis?

Patients receiving prophylaxis for SRMB should be evaluated for the continued presence of risk factors. As the patient improves, the risk factors should, in turn, be reversed, and the need for SRMB prophylaxis should diminish. Factors such as extubation, correction of coagulopathies, discharge from the intensive care setting, and the

ability to take oral feeding advocate for the discontinuation of prophylaxis. Numerous studies have suggested that up to 54% of patients were ordered SRMB prophylaxis outside the ICU setting and without a compelling indication.[271] Erstad and colleagues surveyed 153 institutions within the United States and found that in 65% of the hospitals, >25% of patients remained on SRMB prophylaxis after discharge from the ICU.[272] This can lead to increased costs, the potential of the patient being discharged on medication for which there is no indication, and future potential adverse effects from the medication.[271] Of note, pharmacist-led programs designed to reduce inappropriate acid suppression for SRMB prophylaxis in ICU and non-ICU populations safely reduced prescribing by 58% and 84%, respectively.[257] Because J.S. does not possess any risk factors for SRMB, famotidine should be discontinued at this time.

Lower Gastrointestinal Disorders

Charmaine Rochester-Eyeguokan, Divita Singh, and Abigail Klutts

CORE PRINCIPLES	CHAPTER CASES
INFLAMMATORY BOWEL DISEASE	
1 Inflammatory bowel disease (IBD) is a generic classification for a group of chronic, idiopathic, relapsing inflammatory disorders of the gastrointestinal tract. Symptoms of IBD are thought to result from dysregulation of the mucosal immune system. By convention, IBD is divided into two major disorders, ulcerative colitis (UC) and Crohn disease (CD).	**Case 24-1(Question 1)** **Case 24-2 (Question 1)**

CORE PRINCIPLES		CHAPTER CASES
2	UC is a continuous, superficial mucosal disease isolated to the colon, whereas CD presents in patches, or “skip lesions,” anywhere from the mouth to anus, but more commonly localized to the ileum and large intestine. Extraintestinal manifestations and complications requiring surgery are more common in CD than in UC.	**Case 24-1 (Question 1)** **Case 24-2 (Question 1)**
3	Treatment for both UC and CD are divided into either induction treatment, which controls symptoms, or maintenance treatment, which prevents recurrences. Therapy selection depends on disease severity, location, medication safety profile, cost, and failed or intolerable treatments.	**Case 24-1 (Questions 2, 4, 5, and 8)** **Case 24-2 (Questions 2–6)**
4	Topical 5-aminosalicylic acid (5-ASA) agents, mesalamine and sulfasalazine, are effective for induction and maintenance of mild UC, confined to the rectum (proctitis), or distal colon. They have proved ineffective for CD, but oral sulfasalazine may be used for mild-to-moderate CD with colonic involvement.	**Case 24-1 (Questions 6 and 10)** **Case 24-2 (Question 2)**

CORE PRINCIPLES		CHAPTER CASES
5	Corticosteroids can be used for induction in CD and UC. However, long-term use for maintenance of remission is associated with well-known risks, so alternative therapy is recommended. In no particular order, maintenance therapies for CD include azathioprine, mercaptopurine, methotrexate, adalimumab, certolizumab, infliximab, natalizumab, vedolizumab, and ustekinumab. Maintenance therapies for UC include sulfasalazine, mesalamine, olsalazine, balsalazide, azathioprine, mercaptopurine, infliximab, adalimumab, golimumab, vedolizumab, and tofacitinib.	**Case 24-1 (Questions 3, 7, 9–11)** **Case 24-2 (Questions 3 and 4)**
6	All immunosuppressive medications increase infection risk; therefore, it is necessary to screen for infection before, during, and following discontinuation. Active infections should be treated before starting immunosuppressive therapy. Individuals who need live vaccines should receive them before starting immunosuppressive therapy.	**Case 24-1 (Question 12)** **Case 24-2 (Questions 4–6)**
7	Therapeutic approaches to IBD are rapidly evolving with the advent of biosimilars and novel small-molecule agents, many of which are currently under investigation.	**Case 24-2 (Questions 2 and 3)**

CORE PRINCIPLES		CHAPTER CASES
IRRITABLE BOWEL SYNDROME		
1	Irritable bowel syndrome (IBS) is a common and often debilitating condition that involves abdominal pain, bloating, and defecation associated with a change in bowel habits (usually constipation or diarrhea). Clinicians should reassure patients that the diagnosis is correct, and the condition is benign and treatable.	**Case 24-3 (Questions 1 and 2)**
2	Nonpharmacologic interventions target stress relief and lifestyle modifications. These include patient reassurance, creating a strong physician–patient relationship, improving sleep habits, increasing exercise, and subscribing to a low-FODMAP diet (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols). Psychological interventions can reduce overall symptom burden and should be considered early in IBS management.	**Case 24-3 (Questions 3 and 4)**
3	The treatment goal of IBS management is to improve the predominant symptom type and severity. Treatments for irritable bowel syndrome with constipation (IBS-C) include soluble fiber (psyllium), polyethylene glycol (PEG) laxatives, linaclotide, plecanatide, lubiprostone, tenapanor, and tegaserod.	**Case 24-3 (Question 5)**

CORE PRINCIPLES		CHAPTER CASES
4	Abdominal pain, bloating, or visceral hypersensitivity associated with IBS may respond to antispasmodic agents or tricyclic antidepressants, but the use of selective serotonin-reuptake inhibitors is not recommended.	**Case 24-4 (Question 1)**
5	Treatments for irritable bowel syndrome with diarrhea (IBS-D) include loperamide, eluxadoline, rifaximin, and alosetron. Retreatment with rifaximin in patients who relapsed after initial response is strongly recommended.	**Case 24-4 (Question 2)**

INTRODUCTION

Definition of Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is a nonspecific classification for a group of chronic, idiopathic, noninfectious, relapsing inflammatory disorders of the gastrointestinal (GI) tract. By convention, IBD is divided into two major disorders: ulcerative colitis (UC) and Crohn disease (CD).[1–3]

Epidemiology

The incidence of IBD is increasing globally, particularly among high-income countries and in urban areas.[1-,2,4,5] An estimated 6.8 million people have IBD worldwide,[4] and 3.1 million cases are attributed to the United States, where prevalence is highest.[6] Approximately 10% of patients with IBD are classified as having indeterminate colitis

because they do not present with the distinct clinical features of UC or CD.[7] There is a greater prevalence of IBD among females and Caucasians.[1–4,8] Both UC and CD are considered diseases of the young, with peak incidence from ages 15 to 30 years.[2,5]

Pathophysiology

Under normal conditions, the mucosal immune system interacts with luminal antigens and mucosal bacteria on a continuous basis to maintain a state of controlled inflammation. In IBD, genetic predisposition leads to immune response dysfunction. Proinflammatory cytokines in the gut trigger an "attack" on the colonic mucosa by leukocytes and other factors, leading to edema, ulceration, and destruction of the tissue. Normal immune regulators do not halt this process, and the disease progresses. This can be attributable to a lack of regulatory or suppressor cells, an enhanced numbers of T cells, or both.[9] Studies have demonstrated that an increase of proinflammatory cytokines, chemokines, prostaglandin, and reactive oxygen species leads to increased inflammation and tissue destruction.[1]

IBD has an unclear etiology, but hypotheses include a combination of genetic abnormalities, chronic infection, environmental factors (bacterial, viral, temperate climate, prior appendectomy, and dietary antigens), host or intestinal microbiome interactions, and other abnormalities of immunoregulatory mechanisms.[1] Symptoms result from dysregulation of the mucosal immune system and from an interplay between genetic expression and the environment.[2,10–13]

Several environmental exposures have been associated with IBD. Smoking has been the most consistently studied environmental factor associated with IBD, with smokers having a decreased risk of developing UC but an increased risk of developing CD.[14] The theory of an infectious etiology for IBD remains controversial. Patients may be genetically predisposed to mucosal immune dysregulation, and either normal flora or bacterial pathogens may trigger the inflammatory response that leads to IBD.[15–20] Finally, dietary habits

are thought to play a role in the composition of gut flora and inflammation, particularly with high intake of inflammatory foods such as red meat and highly processed, fatty, or sugary foods.[13] Although no clear causal relationship has yet been established, further investigation on the role of gut flora is ongoing.[21]

Clinical Presentation

A careful patient history, physical examination, and endoscopic and radiologic findings are necessary to diagnose and assess IBD. Blood tests and stool examination help exclude other causes linked to infection, allergies and intolerances, or irritable bowel syndrome (IBS). Erythrocyte sedimentation rate (ESR), fecal calprotectin, and C-reactive protein (CRP) can also aid in the diagnosis, but no single marker is pathognomonic.[22],-[23] Endoscopy is particularly useful to understand the extent of the disease and to differentiate between UC and CD.[24]

Extraintestinal manifestations of IBD can cause significant morbidity and include reactive arthritis, uveitis, ankylosing spondylitis, pyoderma gangrenosum, and primary sclerosing cholangitis. Although their incidence varies, many of the extraintestinal manifestations of UC and CD are similar.[23] Other pathophysiologic similarities and differences are outlined in **Table 24-1**.

Table 24-1
Pathophysiologic Differences Between Ulcerative Colitis and Crohn Disease

Characteristic	Ulcerative Colitis	Crohn Disease
Incidence (per 100,000 person years)	19.2	20.2
Anatomic location	Colon and rectum	Mouth to anus
Distribution	Continuous, superficial, diffuse, mucosal	Segmental, focal, transmural

Characteristic	Ulcerative Colitis	Crohn Disease
Bowel wall	Shortened, loss of haustral markings, generally not thickened	Rigid, thick, edematous, and fibrotic
Gross rectal bleeding	Common	Infrequent
Crypt abscesses	Common	Infrequent
Fissuring with sinus formation	Absent	Common
Noncaseating granulomas	Absent	Common
Strictures	Absent	Common
Abdominal mass	Absent	Common
Abdominal pain	Infrequent	Common
Toxic megacolon	Occasional	Rare
Bowel carcinoma	Greatly increased	Slightly increased
Fistulas	Absent	Advanced complication

ULCERATIVE COLITIS DIAGNOSIS

Patients with UC usually present with proctitis, with symptoms such as bleeding, urgency, tenesmus (urge to defecate), and abdominal pain. The disease cycles between relapsing and remitting, with periods of remission. The inflammation is limited to the mucosa, which presents as friable, granular, and erythematous, with or without ulceration. Despite medical therapy, some patients experience a rapid onset of a progressive type of colitis known as

fulminant disease.[22-,23,25] Long-standing untreated UC is associated with an increased risk of dysplasia and colorectal cancer, which is believed to be due to the chronic inflammation.[26]

After diagnosing UC, the next step is to determine disease severity (see **Table 24-2**). UC activity can be categorized as remission, mild, moderately severe, or fulminant.[22] Acute severe UC is defined in the guidelines as six or more bowel movements a day in the presence of at least one of the following systemic signs of toxicity: tachycardia, fever, anemia (hemoglobin [Hgb] <10.5 g/dL), or elevated inflammatory markers (ESR > 30 mm/hour).[22] Proctitis is usually considered a separate type of UC in which treatment is occasionally needed for constipation.

Table 24-2

Ulcerative Colitis Severity Classification

	Remission	Mild	Moderate-to-Severe	Fulminant
Stools (number/day)	Formed stools	<4	>6	>10
Blood in stools	None	Intermittent	Frequent	Continuous
Urgency	None	Mild, occasional	Often	Continuous
Hemoglobin	Normal	Normal	<75% of normal	Transfusion required
Erythrocyte sedimentation rate	<30	<30	>30	>30
C-reactive protein (mg/L)	Normal	Elevated	Elevated	Elevated
Fecal calprotectin (μg/g)	<150–200	>150–200	>150–200	>150–200
Endoscopy (Mayo subscore)	0–1	1	2–3	3
Ulcerative Colitis Endoscopic Index of Severity	0–1	2–4	5–8	7–8

Reprinted with permission from Rubin DT, Ananthakrishnan AN, Siegel CA, et al. ACG clinical guideline: ulcerative colitis in adults. *Am J Gastroenterol*. 2019;114(3):384–413. © 2019 by The American College of Gastroenterology.

CROHN DISEASE DIAGNOSIS

The cardinal symptoms of CD include diarrhea, abdominal pain, and fatigue. Anemia and weight loss may occur because of slow intestinal bleeding and malabsorption, respectively. There is no single objective criterion that confirms CD diagnosis, but ileocolonoscopy is a key tool for diagnosing and assessing disease activity.[27] Classification of disease severity is included in **Table 24-3**.

Table 24-3
Crohn Disease Severity Classification

	Remission	Mild-to-Moderate	Moderate-to-Severe	Severe-to-Fulminant
Crohn's Disease Activity Index	<150	150–220	220–450	>450
Symptoms	None	May have diarrhea, abdominal pain	Intermittent nausea or vomiting, abdominal pain, or tenderness	Persistent vomiting, significant peritoneal signs such as involuntary guarding or rebound tenderness
Weight loss	None	<10%	≥10%	May be cachectic
Endoscopy		Mild, superficial erosions or ulcers (<10% of the surface area)	Moderate to severely active endoscopic mucosal disease	Severe endoscopic lesions (large >2 cm confluent and deep ulcers)
Simple Endoscopic Score for Crohn's Disease (SES-CD)		≤6	>6	
Crohn's Disease Endoscopic Index of Severity (CDEIS)	<3	≤8	>8	
Complications	None	Not present; can eat and drink without complications	Present, including fever, but no obstruction or significant anemia	Present including intestinal obstruction, anemia, intra-abdominal abscess; frequently hospitalized.
C-reactive protein (mg/L)	May be normal	Usually elevated	Elevated	Elevated
Treatment response	May have responded to medical or surgical therapy (eg, resection). Does not include patients who are steroid dependent	Responds to conventional therapy; surgery is uncommon.	Inadequate response or intolerance to conventional therapy; surgery is common.	Persistent symptoms despite aggressive therapy; surgery is most common.

Although UC is restricted to the colon, CD can exist anywhere along the digestive tract, but areas from the ileum to anus are more common. Unlike UC, ulcerations in CD are patchy and discontinuous, appearing as "skip lesions" with alternating areas of normal and diseased tissue. Penetrating disease is common and includes colonic ulcers, strictures, and fistulas. Abscesses or sepsis can occur because of these complications.[28,29]

As with UC, CD is also a relapsing and remitting disease, where remission involves the resolution of symptoms and objective

inflammatory markers with normalization of bowel habits.[30] An estimated 19% to 38% of individuals have evidence of penetrating disease upon diagnosis, such as enterocutaneous, enterorectal, or enterovaginal fistulae, whereas up to 88% may experience these complications within 20 years of disease.[31]

Overview of Treatment

Treatment of IBD is dependent on disease characteristics (severity, anatomic location, complications), medication characteristics (safety, effectiveness), and individual characteristics (coexisting conditions, adherence, insurance coverage, lifestyle, health literacy, therapy response, and preference). Clinicians should consider failed or intolerable treatments when selecting therapy.[22,28,32]

The goals of IBD therapy include sustained steroid-free remission, mucosal healing, prevention of complications, decreased hospitalizations, and improved quality of life with psychosocial support.[22,28,33] **Table 24-4** displays a list of medications used to treat UC and CD. Although UC and CD share common treatment options, they are often used under different circumstances. **Table 24-5** lists recommendations for pharmacologic use, according to the most recent guidelines from the American College of Gastroenterology. A comparison of aminosalicylate compounds is provided in **Table 24-6**. The treatment algorithms for UC and CD are depicted in **Figures 24-1** and **24-2**, respectively. There are several novel agents in development for IBD, some of which are already approved for other immunologic conditions, such as psoriasis, rheumatoid arthritis, or multiple sclerosis. Novel agents include biosimilars and sphingosine-1 phosphate receptor modulators.[34] Similar to Janus kinase 1, this is a signaling molecule implicated in downstream inflammatory effects. As a small-molecule drug, it is also poised to overcome barriers to biologic use, such as loss of effectiveness over time due to immunogenicity.[35,36]

Table 24-4
Pharmacologic Treatment Options for Irritable Bowel Disease

Drug Class	Mechanism of Action	Warnings	Adverse Drug Reactions	Monitoring
Aminosalicylates				
Mesalamine Enema (Rowasa®) Suppository (Canasa®) Controlled-release microspheres (Pentasa®) Multimatrix, pH-sensitive coating and delayed release (Lialda®) pH-dependent coating, dissolves at pH >7 (Asacol HD®) (Delzicol®) Polymer Matrix/enteric coating, dissolves at pH 6 (Apriso®)	Modulates local chemical mediators of the inflammatory response, especially leukotrienes A free radical scavenger and TNF inhibitor	Hepatitis Pericarditis Myocarditis Acute intolerance syndrome Photosensitivity Renal impairment Hematologic abnormalities Pneumonitis	Headache Burping Abdominal pain Constipation	Renal function CBC Hepatic function Signs and symptoms of worsening, acute intolerance syndrome
Sulfasalazine (Azulfidine®) (Sulfazine®) Oral tablet		Blood dyscrasias Neuromuscular changes Stevens–Johnson syndrome Toxic epidermal necrolysis Fibrosing alveolitis	Skin rash Nausea/vomiting Dyspepsia Anorexia	CBC with differential and liver function tests (before therapy, then every other week for first 3 months of therapy, followed by every month
		Folate deficiency Nausea/vomiting Abdominal pain Hepatic necrosis Drug rash with eosinophilia and systemic symptoms Nephritis Pneumonitis Serious infections Sulfonamide allergy	Oligospermia Headache	for the second 3 months, then once every 3 months thereafter or as clinically indicated) Periodic urinalysis and renal tests Signs of infection, dermatologic toxicity, or hypersensitivity reactions
Olsalazine (Dipentum®) Oral capsule		Colitis, diarrhea	Diarrhea Nausea Abdominal pain	CBC and hepatic function at baseline Renal function at baseline, 6 and 12 months during treatment, and annually thereafter
Balsalazide (Colazal®) Oral capsule		Colitis Acute intolerance syndrome Nephrolithiasis	Headache Abdominal pain Teeth/gum staining Nausea/vomiting	Renal function at baseline, within 6 months of initiation, then annually thereafter LFTs in patients with liver disease
Corticosteroids				
Conventional steroids Oral tablet	Decreases inflammation by suppressing the migration of polymorphonuclear leukocytes and reversing potent inhibitors of T-cell activation and proinflammatory cytokines	Contraindications: Hypersensitivity to prednisone or any component of the formulation Administration of live or live attenuated vaccines with immunosuppressive doses of prednisone Systemic fungal infections Adrenal suppression Anaphylactoid reactions Immunosuppression Kaposi sarcoma	Hyperglycemia Dyslipidemia Hypertension Infection Osteoporosis Psychosis	Blood pressure Weight Chemistries Signs of infection BMD HPA axis suppression Leukopenia and thrombocytopenia (every 6 months when used in combination with AZA) IOP with therapy > 6 weeks Eye examination

		Myopathy Psychiatric disturbances such as euphoria, insomnia, mood swings, personality changes, severe depression, or frank psychotic manifestations		
Budesonide Controlled ileal release, time dependent and pH release ≥5.5 (Entocort EC®) (Ortikos®) Multimatrix structure with gastric acid–resistant coating, pH release ≥7 (Uceris®) Rectal foam (Uceris foam®)	Depresses the activity of endogenous chemical mediators of inflammation		As given earlier, with reduced risk of systemic effects because of local site of action and high first-pass hepatic metabolism	
Immunomodulators				
Thiopurines				
Azathioprine (Imuran®) Oral tablet	Imidazolyl derivative of mercaptopurine, metabolites are incorporated into replicating DNA and halt replication; also block the pathway for purine synthesis	**Malignancy** Leukopenia Thrombocytopenia Neoplasia Infection	Allergic reaction Pancreatitis Myelosuppression Nausea/vomiting Infection Hepatotoxicity	TPMT testing before use CBC with differential (weekly for 1 month, then twice monthly for 2 months); monthly thereafter (monitor more frequently with dosage modifications)
				Total bilirubin LFTs (every 3 months) CrCl Signs of infection and malignancy
6-Mercaptopurine (Purixan®) Oral tablet	Purine antagonist Inhibits DNA and RNA synthesis, specific for the S phase of the cell cycle	Malignancy BMS Hepatotoxicity Immunosuppression Macrophage activation syndrome Photosensitivity		CBC with differential weekly for 1 month, then every 2 weeks for 1 month, then every 1–2 months thereafter LFTs every 3 months Signs of infection and malignancy
Methotrexate (Otrexup®) (Rasuvo®) Subcutaneous injection	Folate antimetabolite that inhibits DNA synthesis, repair, and cellular replication Methotrexate targets the S phase of the cell cycle.	**Serious adverse reactions including death** **BMS** **Serious infections** **Secondary malignancy** **Tumor lysis syndrome** **Renal toxicity and increased toxicity with renal impairment** **GI toxicity** **Hepatotoxicity** **Pneumonitis Hypersensitivity dermatologic reactions** **Opportunistic infections** Increased risk of malignancy, including skin cancer and lymphoma	Pancreatitis Nausea/vomiting Hepatotoxicity Pulmonary toxicity BMS	Pregnancy: Contraindicated in pregnancy due to embryo-fetal toxicity, including fetal death

Calcineurin Inhibitor				
Cyclosporine (Gengraf®) (Neoral®) (Sandimmune®) Oral tablet	Inhibits the production and release of IL-2 and inhibits IL-2-induced activation of resting T lymphocytes	**Infections** **Immunosuppression** **Hypertension** **Nephrotoxicity** **Malignancy** **Neurotoxicity** Gingival hyperplasia Hepatotoxicity Hyperkalemia Hyperuricemia	Nausea Headache Hypertension Nephrotoxicity Edema Paresthesia Hirsutism Elevated triglycerides	Renal function Blood pressure periodically and following medication changes Signs and symptoms of: Infection Hepatotoxicity Secondary malignancy Diabetes mellitus Hypersensitivity reactions (IV) Progressive cognitive or motor deficits MRI may be required to diagnose posterior reversible encephalopathy syndrome (PRES).
Biologics				
TNF Blockers				
Adalimumab (Humira®) Subcutaneous injection Adalimumab-atto (Amjevita®) Adalimumab-adbm (Cyltezo®) Adalimumab-adaz (Hyrimoz®)	Binds to TNF-α and blocks the interaction with p55 and p75 cell-surface TNF receptors	**Serious infection leading to hospitalization or death** **Lymphoma and other malignancies, particularly in combination with thiopurines** Hepatitis B reactivation New or worsening demyelinating disease New or worsening CHF Lupus-like syndrome Hypersensitivity reaction Cytopenias	URI Headache Rash Injection site reaction	Perform test for latent TB; if positive, start treatment for TB before initiating. Monitor all patients for active TB during treatment, even if the initial latent TB test result is negative.
Certolizumab pegol (Cimzia®) Subcutaneous injection	Binds to and selectively neutralizes TNF-α to inhibit receptor binding		URI Rash UTI Injection site reaction	
Golimumab (Simponi®) Subcutaneous injection	Binds to and inhibits TNF-α		URI Nasopharyngitis Injection site reaction	
Infliximab (Remicade®) IV infusion Infliximab-axxq (Avsola®) Infliximab-dyyb (Inflectra®) Infliximab-qbtx (Ixifi®) Infliximab-abda (Renflexis®)	Binds to and selectively neutralizes TNF-α to inhibit receptor binding		URI Infusion-related reactions Headache Abdominal pain	

Anti-Integrins				
Natalizumab (Tysabri®) IV infusion	Binds to α4-subunit of αβ1 and αβ integrins to inhibit leukocyte binding to receptors	**PML** Infection Hypersensitivity reaction Hepatotoxicity	Headache Fatigue Arthralgia Pain in extremities UTI Lower respiratory infection Gastroenteritis Vaginitis Depression Abdominal discomfort Diarrhea Rash Nausea	Testing for anti-JCV before initiation and every 6 months until treatment is stopped, or the result is positive Signs and symptoms of hepatotoxicity
Vedolizumab (Entyvio®) IV infusion	Selectively binds to α4 β7 integrin to interrupt cell signaling and inhibit T-cell migration	PML cannot be ruled out. Infection Hypersensitivity reaction Hepatotoxicity	Headache Fatigue Arthralgia Pain in extremities URI Lower respiratory infection Nasopharyngitis Nausea Pyrexia Cough Back pain Rash Pruritus Sinusitis Oropharyngeal pain	Signs and symptoms of hepatotoxicity
Interleukin Antagonist				
Ustekinumab (Stelara®) IV infusion for induction Subcutaneous injection for maintenance	Selectively binds to the p40 subunit on IL-12 and IL-23 cytokines to interrupt natural killer cell and CD4+ T-cell activation	Serious infection requiring hospitalization Malignancy Hypersensitivity reaction RPLS (rare)	Vomiting Nasopharyngitis Injection site erythema Vulvovaginal candidiasis Mycotic infection Bronchitis Pruritus UTI Sinusitis	TB screen before and throughout treatment
Novel Small Molecules				
Janus Kinase Inhibitor				
Tofacitinib (Xeljanz®) Oral tablet	Inhibits JAK1 and JAK3 signaling to modulate intracellular activity like gene expression	**Serious infection requiring hospitalization** **Lymphoma and other malignancies**	Nasopharyngitis Elevated cholesterol Headache URI	Perform test for latent TB; if result is positive, start treatment for TB before initiating.
		EBV-associated post-(renal) transplant lymphoproliferative disorder, with concomitant immunosuppressive medications GI perforation	Increased blood creatinine phosphokinase Rash Diarrhea Herpes zoster	Monitor all patients for active TB during treatment, even if the initial latent TB test result is negative. Laboratory monitoring recommended to detect changes in lymphocytes, neutrophils, Hgb, LFTs, and lipids
Bold indicates boxed warning				

AZA, azathioprine; BMD, bone mineral density; BMS, bone marrow suppression; CBC, complete blood count; CHF, congestive heart failure; CrCl, creatinine

clearance; DNA, deoxyribonucleic acid; EBV, Epstein–Barr virus; GI, gastrointestinal; Hgb, hemoglobin; HPA, hypothalamic–pituitary–adrenal axis; IL, interleukin; IOP, intraocular pressure; IV, intravenous; JAK, Janus kinase; JCV, John Cunningham virus; LFT, liver function test; MRI, magnetic resonance imaging; PML, progressive multifocal leukoencephalopathy; RNA, ribonucleic acid; RPLS, reversible posterior leukoencephalopathy syndrome; TB, tuberculosis; TNF, tumor necrosis factor; URI, upper respiratory infection; UTI, urinary tract infection.

Table 24-5
Pharmacotherapy for Inflammatory Bowel Disease

Drug	Indication	Quality of Evidence per ACG	Recommendation per ACG	Dose	Therapeutic Considerations
	UC: Mildly active maintenance of remission	Moderate	Strong	Apriso®: 1.5 g PO every morning Delzicol®: 1.6 g PO in 2–4 divided doses Lialda®: 2.4 g PO daily Pentasa®: 1 g PO qid	
	UC: Moderate to severely active induction of remission (do not recommend combination with TNF blocker therapy)	Conditional	Low	Mesalamine Enema Rowasa® 4 g rectal enema at bedtime, retained overnight for 8 hours. Asacol HD®: 1.6 g PO tid Delzicol®: 800 mg PO tid Lialda®: 2.4 or 4.8 g PO daily Pentasa®: 1 g PO qid	
	CD: Not recommended	Strong	Moderate		
Olsalazine Dipentum®	UC: Mildly active induction of remission	Moderate	Strong	2–3 g/day PO in 2–4 divided doses	
	UC: Mildly active maintenance of remission	Moderate	Strong	500 mg PO bid	
	UC: Moderate to severely active induction of remission (do not recommend combination with TNF blocker therapy)	Conditional	Low	2–3 g/day PO in 2–4 divided doses	
	UC: Moderate to severely active maintenance of remission (do not recommend combination with TNF blocker therapy)	Conditional	Low	500 mg PO bid	
Balsalazide Colazal®	UC: Mildly active induction of remission	Moderate	Strong	2.25 g PO tid	Not recommended in combination with TNF blockers for moderate to severely active UC
	UC: Mildly active maintenance of remission	Moderate	Strong		
	UC: Moderate to severely active induction of remission	Conditional	Low	1.5–3 g PO bid	
	UC: Moderate to severely active maintenance of remission	Conditional	Low		
Corticosteroids					
Conventional oral steroids	UC: Mildly active induction of remission	Low	Strong	Prednisone PO 40–60 mg/day	Use in patients who failed 5-ASA. Goal to avoid chronic use in IBD Expect clinical response in 5–7 days.

	UC: Mildly active maintenance of remission—**not recommended**	Strong	Moderate		
	UC: Moderate to severely active induction of remission	Strong	Moderate	Prednisone PO 40–60 mg/day	
	UC: Moderate to severely active maintenance of remission—**not recommended**	Strong	Moderate		
	UC: Severely active UC in hospitalized patient induction of remission	Strong	Low	Methylprednisolone 60 mg/day or Hydrocortisone 100 mg three to four times per day	Goal to avoid chronic use in IBD Expect clinical response in 3–5 days.
	CD: Moderate to severely active symptom relief for short-term use	Strong	Moderate	Oral prednisone equivalent 40–60 mg daily tapered weekly. Not to exceed 60 mg equivalent or 3-month duration	Goal to avoid chronic use or steroid dependence
	CD: Intravenous use for severe or fulminant disease	Conditional	Moderate	Equivalent to hydrocortisone 300–400 mg/day or methylprednisolone 48–60 mg/day	
	CD: Not recommended for long-term maintenance	Strong	Moderate		
Budesonide Entocort EC® Ortikos® Uceris®	UC: Mildly active induction of remission	Strong	Moderate	Uceris®: 9 mg PO daily Uceris Foam®: 2 mg per rectum bid	Consider in patients who failed 5-ASA. Rectal formulations can be considered for symptoms of diarrhea and rectal bleeding.
	UC: Moderate to severely active induction of remission	Strong	Moderate		Rectal formulations can be considered for symptoms of diarrhea and rectal bleeding.
	CD: Mild to moderately active and low-risk ileocecal disease for induction of symptomatic remission	Strong	Low	Uceris®: 9 mg PO daily	Not recommended to maintain remission beyond 4 months
Immunomodulators					
Thiopurines (AZA and 6-MP) AZA Imuran® 6-MP Purixan®	UC: Moderate to severely active induction of remission	Low	Strong	6-MP: 50 mg PO once daily; titrate up to 1.5 mg/kg/day AZA: 2.5 mg/kg/day PO	**Do not use monotherapy in UC.** Recommended in combination with infliximab Pharmacogenomic testing for TPMT polymorphism now commonly performed before initiating drug Avoid use with xanthine oxidase inhibitors.

	UC: Mildly active maintenance of remission—**not recommended**	Strong	Moderate		
	UC: Moderate to severely active induction of remission	Strong	Moderate	Prednisone PO 40–60 mg/day	
	UC: Moderate to severely active maintenance of remission—**not recommended**	Strong	Moderate		
	UC: Severely active UC in hospitalized patient induction of remission	Strong	Low	Methylprednisolone 60 mg/day or Hydrocortisone 100 mg three to four times per day	Goal to avoid chronic use in IBD Expect clinical response in 3–5 days.
	CD: Moderate to severely active symptom relief for short-term use	Strong	Moderate	Oral prednisone equivalent 40–60 mg daily tapered weekly. Not to exceed 60 mg equivalent or 3-month duration	Goal to avoid chronic use or steroid dependence
	CD: Intravenous use for severe or fulminant disease	Conditional	Moderate	Equivalent to hydrocortisone 300–400 mg/day or methylprednisolone 48–60 mg/day	
	CD: Not recommended for long-term maintenance	Strong	Moderate		
Budesonide Entocort EC® Ortikos® Uceris®	UC: Mildly active induction of remission	Strong	Moderate	Uceris®: 9 mg PO daily Uceris Foam®: 2 mg per rectum bid	Consider in patients who failed 5-ASA. Rectal formulations can be considered for symptoms of diarrhea and rectal bleeding.
	UC: Moderate to severely active induction of remission	Strong	Moderate		Rectal formulations can be considered for symptoms of diarrhea and rectal bleeding.
	CD: Mild to moderately active and low-risk ileocecal disease for induction of symptomatic remission	Strong	Low	Uceris®: 9 mg PO daily	Not recommended to maintain remission beyond 4 months
Immunomodulators					
Thiopurines (AZA and 6-MP) AZA Imuran® 6-MP Purixan®	UC: Moderate to severely active induction of remission	Low	Strong	6-MP: 50 mg PO once daily; titrate up to 1.5 mg/kg/day AZA: 2.5 mg/kg/day PO	**Do not use monotherapy in UC.** Recommended in combination with infliximab Pharmacogenomic testing for TPMT polymorphism now commonly performed before initiating drug Avoid use with xanthine oxidase inhibitors.

	UC: Moderate to severely active maintenance of remission	Low	Conditional	6-MP: 1–1.5 mg/kg/day PO AZA: 2.5 mg /kg/day PO	Recommended for patients who achieved remission with corticosteroid
	UC: Severely active UC in hospitalized patient maintenance of remission	Low	Conditional	6-MP: 1–1.5 mg/kg/day PO AZA: 2.5 mg /kg/day PO	Use in patients who achieved remission through cyclosporine treatment.
	CD: Moderate to severely active as steroid-sparing agents	Strong	Low	6-MP: 0.75–1.5 mg/kg/day PO AZA: 1.5–2.5 mg/kg/day PO	Effective steroid-sparing option, or in the case of steroid dependence, with or without TNF blocker therapy
					Not to be used for induction because of slow time to clinical response, up to 12 weeks If used in combination with infliximab, dose may be reduced to minimize adverse effects.
	CD: Moderate to severely active for maintenance of remission, particularly following induced remission using steroids	Strong	Moderate		
	CD: Moderate to severely active, in combination with infliximab is more effective than is monotherapy in naive patients	Strong	High		
	CD: Fistulizing disease	Strong	Low		
Methotrexate Otrexup® Rasuvo®	UC: Moderate to severely active induction of remission (do not use monotherapy)	Low	Strong	25 mg IM/SQ weekly for 4 months	Usually reserved for patients who have failed 6-MP/AZA UC data extrapolated from CD studies (use in combo with a TNF blocker) Known teratogen: Administer to females only if highly effective contraception is in place. Males should avoid unprotected sex with a female of reproductive potential during and at least 3 months after use. Administer with folic acid 1 mg PO daily to reduce GI, hepatic, and hematologic adverse effects associated with methotrexate.

	UC: Moderate to severely active maintenance of remission **(do not recommend)**	Low	Conditional		
	CD: Moderate to severely active for alleviating signs and symptoms in steroid-dependent CD for maintaining remission	Conditional	Low	25 mg IM/SQ weekly for 4 months, then consider 15 mg weekly thereafter	
	CD: Combined with a TNF blocker to reduce immunogenicity and loss of response	Strong	Moderate	12.5 mg PO weekly	
Cyclosporine Gengraf® Neoral® Sandimmune®	UC: Severely active UC in hospitalized patient induction of remission (use if not responding to 3–5 days of IV corticosteroids)	Moderate	Strong	2 mg/kg/day continuous infusion over 25 hours Switch to cyclosporine PO 2.3–3 mg/kg every 12 hours.	IV route preferable in hospitalized patients
	UC: Severely active UC in hospitalized patient maintenance of remission (do not use cyclosporine—switch to thiopurines or vedolizumab)	Low	Conditional		
	CD: Not recommended	Strong	Moderate		
Biologics					
Infliximab Avsola® Inflectra® Ixifi® Remicade® Renflexis®	UC: Moderate to severely active induction of remission	High	Strong	5 mg/kg IV at weeks 0, 2, and 6; then every 8 weeks thereafter	Scheduled treatment preferred to episodic treatment to maintain response and decrease delayed infusion reactions Pediatrics: Use has not been studied in children younger than 6 years. Pregnancy: Use only if benefit outweighs risk. Drug has been found in infant serum up to 6 months post birth. May be reserved in CD for steroid-resistant or refractory cases and those refractory to thiopurines or methotrexate May be used in combination with thiopurines, but with increased risk of adverse effects Combination use is not recommended for other TNF blockers.

	UC: Moderate to severely active maintenance of remission (continue medication)	Moderate	Strong		
	UC: Severely active UC in hospitalized patient induction of remission (use if not responding to 3–5 days of IV corticosteroids)	Moderate	Strong		
	UC: Severely active UC in hospitalized patient maintenance of remission (continue if achieved remission via Infliximab treatment)	Moderate	Strong		
	CD: Moderate to severely active for induction and maintenance of TNF blocker–induced remission	Strong	Moderate-to-high	5 mg/kg IV at 0, 2, and 6 weeks, then every 8 weeks thereafter; dose may be increased to 10 mg/kg for initial responders who later lose response	
	CD: Fulminant disease	Conditional	Low		
	CD: Perianal fistulas	Strong	Moderate		
	CD: Enterocutaneous and rectovaginal fistulas	Strong	Moderate		
Adalimumab Amjevita® Cyltezo® Humira® Hyrimoz®	UC: Moderate to severely active induction of remission	High	Strong	160 mg SQ day 1, 80 mg SQ day 14, 40 mg SQ day 29 then every other week thereafter	Available as a prefilled pen for self-administration Pediatrics: Use has not been studied in children younger than 4 years. Pregnancy: Use only if benefit outweighs risk. Consider enrollment in pregnancy registry. May be reserved for steroid-resistant CD or cases refractory to thiopurines or methotrexate
	UC: Moderate to severely active maintenance of remission (continue medication)	Moderate	Strong	40 mg SQ every other week	
	CD: Moderate to severely active for induction and maintenance of TNF blocker–induced remission	Strong	Moderate-to-high	Day 1: 160 mg Day 15: 80 mg Day 29: 40 mg every other week	
	CD: Perianal fistulas	Strong	Low		

Certolizumab pegol Cimzia®	CD: Moderate to severely active for induction and maintenance of TNF blocker–induced remission	Strong	Moderate-to-high	400 mg SQ at weeks 0, 2, and 4; then every 4 weeks thereafter	Pediatrics: Not indicated Pregnancy: Use only if benefit outweighs risk. Consider enrollment in pregnancy registry. May be reserved for steroid-resistant CD or cases refractory to thiopurines or methotrexate
	CD: Perianal fistulas	Strong	Low		
Golimumab Simponi®	UC: Moderate to severely active induction of remission	High	Strong	200 mg SQ at week 0, then 100 mg at week 2	Test for latent TB; if result is positive, start treatment for TB before starting golimumab.
	UC: Moderate to severely active maintenance of remission (continue medication)	Moderate	Strong	100 mg SQ every 4 weeks	
Natalizumab Tysabri®	CD: Moderate to severely active for induction of symptomatic response and remission	Strong	High	300 mg IV over 1 hour every 4 weeks	Requires TOUCH Prescribing Program, which is a restricted distribution program because of cases of PML
					Pediatrics: Not indicated Pregnancy: Animal reproductive studies have shown adverse effects on the fetus. Use only if benefit outweighs risk. Consider enrollment in pregnancy registry.
	CD: Moderate to severely active maintenance in natalizumab-induced remission; only if serum antibody to John Cunningham virus is negative	Strong	Moderate		
Vedolizumab Entyvio®	UC: Moderate to severely active induction of remission	Moderate	Strong	300 mg IV over 30 minutes at weeks 0, 2, and 6, and every 8 weeks thereafter	No cases of PML were observed in clinical trials; and does not currently require a restricted distribution program. Favorable side effect profile when compared to other systemic immunosuppression

					Pediatrics: Not indicated Pregnancy: Use only if benefit outweighs risk. Consider enrollment in pregnancy registry.
	UC: Moderate to severely active maintenance of remission (continue medication)	Moderate	Strong	300 mg IV every 8 weeks	
	UC: Severely active UC in hospitalized patient maintenance of remission (use in patients who achieved remission through cyclosporine treatment)	Low	Conditional	300 mg IV every 8 weeks	
	CD: Moderate to severely active and objective evidence of active disease with or without an immunomodulator for induction of symptomatic remission	Strong	High	300 mg IV over 30 minutes at weeks 0, 2, and 6	
	CD: Maintenance of remission of vedolizumab-induced remission	Conditional	Moderate	300 mg IV over 30 minutes every 8 weeks	
Ustekinumab Stelara®	CD: Moderate-to-severe disease in patients who have failed previous treatment with corticosteroids, thiopurines, methotrexate, or TNF blockers or who have no prior experience with TNF blockers	Strong	High	Weight-based induction dosing, administered IV as a single dose: ≤55 kg: 260 mg >55–85 kg: 390 mg >85 kg: 520 mg	Pediatrics: Not indicated Pregnancy: Use only if benefit outweighs risk. Consider enrollment in pregnancy registry.
	CD: Maintenance of remission of ustekinumab-induced remission	Conditional	Moderate	90-mg SQ injection every 8 weeks starting 8 weeks after the induction dose	
JAK Inhibitor					
Tofacitinib Xeljanz®	UC: Moderate to severely active induction of remission	Moderate	Strong	10 mg PO bid for 8 weeks; based on therapeutic response, may continue 10 mg bid for up to 16 weeks XR: 2 mg PO once daily for at least 8 weeks; evaluate patients and transition to maintenance therapy depending on therapeutic response. If needed, continue 22 mg q day for up to 16 weeks.	Test for latent TB; if result is positive, start treatment for TB before starting tofacitinib.
	UC: Moderate to severely active maintenance of remission (continue medication)	Moderate	Strong	5 mg PO bid XR: 11 mg PO daily	For patients with loss of response during maintenance treatment, a dosage of 10 mg bid (or XR 22 mg daily) may be considered and limited to the shortest duration.

5-ASA, 5-aminosalicylic acid; 6-MP, 6-mercaptopurine; ACG, American College of Gastroenterology; ADR, adverse drug reaction; AZA azathioprine; BID, two times daily; CD, Crohn disease; CNS, central nervous system; GI, gastrointestinal; HA, headache; IM, intramuscularly; IV, intravenously; JAK, Janus kinase; N/V, nausea/vomiting; PML, progressive multifocal leukoencephalopathy; PO, orally; PR, per rectum; q day, daily; qid, four times daily; SQ, subcutaneously; TB, tuberculosis; tid, three times daily; TNF, tumor necrosis factor; TPMT, thiopurine methyltransferase; UC, ulcerative colitis; XR, extended release.

ECCO guidelines on

therapeutics in Crohn's disease: medical treatment. *J Crohns Colitis*. 2020;14(1):4–22. doi:10.1093/ecco- jcc/jjz180.)

Although it has been theorized that an abnormal immune response to normal flora can lead to inflammation in genetically susceptible individuals, the American College of Gastroenterology guidelines for CD recommend against using probiotics and long-term antibacterial therapy for treatment.[28,88] The American College of Gastroenterology guidelines for UC do not make a recommendation about probiotic use.[22] Antibiotics are still recommended where otherwise indicated, for example, in the case of pyogenic complications. [22,28] Metronidazole is often used to treat, or, in unique cases, prevent bacterial infections in the GI tract. Common adverse effects with chronic, high-dose metronidazole include metallic taste and peripheral neuropathy.[89]

NUTRITION

There is no single diet recommended for all patients with IBD,[22,28] although specific protein requirements are recommended for adults with an active flare (1.2–1.5 g/kg/day).[88] Evidence is insufficient to suggest that diet alone can induce or maintain remission,[90] except for pediatric patients with CD where guidelines may recommend exclusive enteral nutrition.[88,91,92] Total parenteral and enteral nutrition for adults is only recommended in accordance with the American Society for Parenteral and Enteral Nutrition Guidelines (ASPEN).[93] Individuals with IBD should meet with a dietician as part of a holistic approach to avoid nutritional deficiencies, dehydration, and exacerbation of flares.[22,28,32] General dietary guidance includes eating a healthy, well-balanced diet rich in fruits, vegetables, and omega-3 fatty acids, while limiting foods that promote intestinal inflammation or discomfort such as caffeine, alcohol, sugar, saturated fats, and insoluble fiber.[88,94] Patients should be screened for malnutrition at diagnosis and regularly thereafter. Vitamin deficiencies are common, especially if ileal involvement is extensive or resection has been performed.

SUPPORTIVE CARE

Symptomatic management of IBD is important to the patient's quality of life. This includes pain relief and diarrhea control. For pain relief, patients should avoid medications that upset the GI tract such as nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids. Loperamide or diphenoxylate with atropine may be used to treat mild symptoms provided that alternative causes for diarrhea have been ruled out, including obstruction or toxic megacolon. Severe worsening of symptoms and abdominal distension may indicate toxic megacolon caused by the inability to rapidly empty secretory products of the bowel.[3] Patients with active IBD are more likely to have feelings of distress or lack of self-control compared to the general population.[2] Therefore, psychosocial support may be needed to improve overall quality of life.

SURGERY

Surgery is indicated when the patient fails to respond to medical management; demonstrates intestinal complications such as perforation, obstruction, hemorrhage, stricture, toxic megacolon, or fistula formation; fails to grow and develop at a normal rate; or exhibits carcinoma on biopsy.[22,95] The surgical procedure of choice depends on the indication, but may include a subtotal or a total colectomy with end ileostomy. For patients with UC, surgery is often curative. In contrast, in patients with CD, the disease recurrence after surgery is common and anatomically correlates with the original pattern of the disease.[23]

ULCERATIVE COLITIS

Pathophysiology and Clinical Presentation

CASE 24-1

QUESTION 1: A.C., a 24-year-old female college student, has had episodic, watery diarrhea, and colicky abdominal pain relieved by defecation for the past 9 months. Eight weeks before admission, the diarrhea increased to three to five semiformed stools daily. The frequency of the stools gradually increased to 7 to 10 times a day 1 week ago. At that time, A.C. noted bright red blood in the stools. Stool frequency has now increased to 12 to 15 per day, although the volume of each stool is estimated to be only "one-half cupful." She feels a great urgency to defecate, even though the volume is small. She has not traveled outside the United States, has not been camping, and has not taken any antibiotics within the past 6 months. She is allergic to sulfa.

A.C. reports of anorexia and a 10-pound (4.53-kg) weight loss during the previous 2 months. For the past 4 months, she has had intermittent swelling, warmth, and tenderness of the left knee, which is unassociated with trauma. She denies any skin rashes or any difficulties with her vision. A review of other body systems and social and family history are noncontributory.

A.C. appears to be slightly anxious and fatigued, with normal body habitus. She is 65 inches (165.01 cm) tall and weighs 112.44 pounds (51 kg). Her temperature is 100 °F (37.78 °C); her pulse rate is 105 beats/minute. Physical examination is normal except for swelling, warmth, and tenderness of the left knee, suggestive of arthritis.

Stool examination shows a watery effluent that contains numerous red and white cells with no trophozoites. Stool cultures and an amebiasis indirect hemagglutination test result are negative. Other laboratory values include the following results:

Hematocrit (Hct), 30%
Hgb, 8.1 g/dL
White blood cell (WBC) count, 17,500/μL with 82% polymorphonuclear neutrophils (PMNs)
ESR, 72 mm/hour
Serum albumin, 2.8 g/dL
Alanine aminotransferase (ALT), 33 units/mL
Sigmoidoscopy showed evidence of granular, edematous, and friable mucosa with continuous ulcerations extending from the anus throughout the colon.

What is the most probable cause of A.C.'s diarrheal illness, and what is the evidence for this?

A.C.'s presentation is typical of a patient with new-onset UC. Drug-induced (pseudomembranous colitis) and infectious (parasitic) causes of diarrhea have been ruled out by history, including no travel outside the United States, no antibiotic use, and stool examination. As discussed previously, UC is characterized by inflammation of the

mucosal layer of the colon and rectum.[1] The inflammation does not extend beyond the submucosa, so transmural ulcers are rare. On examination, the mucosa appeared erythematous and friable. Differentiation from CD is made by endoscopic and radiologic evidence of continuous distribution of pathologic disease (as opposed to segmental or skip lesions), as well as the anatomic location (confined to the colon and rectum).

A.C. presents with the classic triad of UC clinical symptoms: chronic diarrhea, rectal bleeding, and abdominal pain. Diarrhea is secondary to decreased colonic absorption of water and electrolytes and diminished colonic segmental contractions that normally serve to decrease the flow of bowel content. A good indication of disease severity is the volume of stool passed per day.[22] Incontinence and nocturnal diarrhea commonly occur as disease severity progresses. Stools are usually soft, mushy, formed, and often contain small amounts of mucus mixed with blood. In addition to diarrhea, the malabsorption of water and electrolytes causes dehydration, weight loss (as observed in A.C.), and electrolyte disturbances.

A.C.'s rectal bleeding is secondary to colonic mucosal erosions and occurs in most patients with UC. Bright red blood mixed in the stools indicates a colonic origin, whereas blood-streaked stools indicate an anal or a rectal origin. The anemia associated with UC is secondary to rectal bleeding. It presents as a hemorrhagic or an iron-deficiency anemia, depending on the acuteness of the bleeding. Hgb and Hct laboratory values often are decreased, as in A.C.'s case. Chronic inflammatory disease–induced hypoalbuminemia is often exacerbated by malnutrition.

A.C.'s abdominal pain and cramping are caused by spasm of the irritated and inflamed colon. This abdominal pain is commonly associated with an urgency to defecate. As illustrated by A.C., the pain is usually relieved with defecation, even though the stool volume may be small.

A.C.'s arthritis and elevated ALT are indicative of the extraintestinal manifestations that occur in IBD.[96] Her nonspecific symptoms (ie, anorexia, fatigue, weight loss, anxiety, tachycardia) could become profound during an exacerbation of UC. Fever,

leukocytosis, and increased ESR are also systemic manifestations of an inflammatory disease. Rehydration is important to ensure fluid balance and maintain good renal function. Given her frequency of stools, Hgb, tachycardia, and elevated ESR, A.C.'s disease would be classified as acute severe UC. Patients with acute severe UC should be admitted to the hospital for inpatient management.

Case 24-1, Question 2: How should A.C.'s diarrhea be managed?

Treatment of the diarrhea associated with UC is often difficult. For patients with mild-to-moderate disease, antidiarrheals, such as loperamide or diphenoxylate with atropine, used as needed, may help minimize chronic diarrhea. Extreme caution must be used, especially in patients with severe disease because of the chance of inducing toxic megacolon, a life-threatening condition, and medical emergency. For this reason, antidiarrheals are best avoided in patients with severe active disease, such as with A.C. Bulk-forming agents (ie, psyllium) may be helpful for patients with constipation caused by ulcerative proctitis.[97]

Case 24-1, Question 3: What agents can be used to induce disease remission in A.C.?

Systemic intravenous (IV) corticosteroids are the most effective agents to induce remission of acute severe UC. Patients with acute severe UC should be started on methylprednisolone 60 mg IV per day or hydrocortisone 100 mg IV three to four times a day to induce remission. Up to 67% of patients with acute severe UC respond to steroid treatment.[98] Topical corticosteroids can be added for symptom control with distal involvement.

Infliximab or cyclosporine should be considered for induction of remission as rescue therapy in patients with acute severe UC who are hospitalized and not responding to 3 to 5 days of IV corticosteroid therapy. Notably, additional response is unlikely after 7 days of IV corticosteroid therapy.[22] When choosing between

infliximab and cyclosporine for rescue therapy, it is important to keep in mind that rates of treatment failure and colectomy are higher in patients receiving cyclosporine who have previously failed immunomodulator therapy; therefore, infliximab may be a preferred agent in such patients. In addition, in patients with albumin <2.3 g/dL, infliximab is the preferred agent because of more favorable treatment results.[99]

Given that A.C. is of childbearing age, a pregnancy test should be obtained, and results taken into consideration when choosing current and future drug therapy, particularly if pregnant or breastfeeding (see Chapter 49, Obstetric Drug Therapy).[100]

Case 24-1, Question 4: Methylprednisolone at a dosage of 40 mg IV every 6 hours is ordered. What are the treatment goals for A.C.?

The goal of parenteral corticosteroid therapy for A.C. is to achieve a rapid therapeutic response. Monitoring should include assessment of vital signs and physical examination to assess abdominal distension, abdominal tenderness, frequency of bowel movements, presence of visible blood, abdominal pain, and systemic symptoms.

The Oxford Criteria is used to identify patients who are not responding to IV corticosteroid therapy and includes the following parameters: having more than eight bowel movements per day on day 3 of IV corticosteroid treatment, or three to eight bowel movements per day, and CRP >45 mg/L. Patients who are nonresponders to IV corticosteroid therapy are more likely to require colectomy than do patients with partial or complete response. Additional parameters that can be used to predict nonresponders to IV corticosteroid therapy include patients with elevated ESR >75 mm/hour, elevated temperature, and hypoalbuminemia.[101,102]

Patients who are poor responders to IV corticosteroid therapy should be evaluated for surgical intervention. Surgery is indicated in patients who develop toxic megacolon, perforation, or massive hemorrhage. It is important not to delay a surgical consultation in patients who are poor responders because that can lead to poor

clinical outcomes. Surgical treatment options include a subtotal or total colectomy with end ileostomy. It is important not to delay surgical interventions in patients who otherwise are initiated on infliximab or cyclosporine rescue therapy.[103]

Poorly nourished patients in whom oral intake is expected to be absent for >7 days should receive parenteral nutrition, and treatment should be continued until oral feeding is tolerated.[104] An adequate response is defined as resolution of fever and tachycardia, improved patient well-being, and less abdominal tenderness on palpation. Diarrhea is usually considered to be resolved with four bowel movements or more daily. Usually by this point, stools are rarely formed, and the patient is no longer observing bloody stools. Once A.C.'s symptoms are controlled, the goal should be to switch to oral corticosteroids and discharge her from the hospital.

Case 24-1, Question 5: A.C. is responding well to methylprednisolone. She is afebrile, her abdominal pain is reduced (to a score of 4 on a 1–10 scale), and her diarrhea is decreasing. When is the oral route of corticosteroid administration indicated in UC? What are the most appropriate dosages?

Oral corticosteroids are effective for the initial treatment of mild-to-moderate acute UC.[105] In addition, patients on parenteral corticosteroids for severe exacerbation should be switched to oral corticosteroids once a satisfactory initial response has been achieved. The usual dose of oral prednisone is 40 to 60 mg/day because doses >60 mg/day have shown to provide no additional therapeutic value, while causing more adverse effects.

Case 24-1, Question 6: What if A.C.'s UC was limited to the distal colon or rectum? Would topical corticosteroids be indicated? When should other topical agents be considered for A.C.?

It is important to select organ-specific treatment options compared to systemic therapies when symptoms are limited to the distal colon or rectum. Topically administered 5-aminosalicylic acid (5-ASA) and corticosteroids, in the form of suppositories, foams, and retention

enemas, are effective in the management of acute, mild-to-moderate UC that is limited to the distal colon and rectum.[106]

The desired outcome for medications administered via this topical route is to provide a higher concentration of drug to the diseased mucosal area, exerting a local anti-inflammatory effect, while minimizing systemic side effects. Unfortunately, variable but significant systemic absorption (up to 90%) and adrenal suppression occur from the topical administration of corticosteroid to the rectum and distal colon.[107] Therefore, the beneficial effects produced by topical use of these agents may accrue from both systemic and local effects. The low incidence of corticosteroid side effects associated with topical administration may be related to both the low doses and the infrequent administration (daily to twice daily) needed to control mild acute UC.

5-ASA suppositories and enemas are preferred over topical corticosteroids for the treatment of distal UC and proctitis because they produce higher remission rates in proctitis and effectively maintain remission of distal UC.[107] For distal UC, therapy is initiated with a nightly enema (4 g of mesalamine), and the response should be evaluated in 3 to 4 weeks. For mild acute proctitis, administering one suppository of 5-ASA twice daily for 3 to 6 weeks is sufficient to induce disease remission. Improvement should be seen in 2 to 3 weeks, and therapy should be maintained until complete remission is achieved. If remission is reached, therapy can then be tapered to one suppository or enema, two to three times weekly. Therapy with oral plus topical mesalamine showed greater efficacy than either alone in achieving remission of distal UC or proctitis.[106]

CASE 24-1, QUESTION 7: What corticosteroid adverse effects should the clinician monitor in A.C.?

Corticosteroid side effects and precautions for use often limit the therapeutic effectiveness of these agents and should never be overlooked.[108] Certain glucocorticoid adverse effects are of particular importance in patients with IBD in that they may mimic, mask, or

intensify symptoms and complications of this disease. For example, the symptoms of peritonitis, one of the major complications of intestinal perforation, may be masked by corticosteroids. Other deleterious effects of corticosteroids include hyperglycemia, avascular necrosis, cataract formation, and central nervous system effects, including mood disorders, insomnia, psychoses, and euphoria.

Patients with IBD are at risk for decreased bone mineral density, which is exacerbated by prolonged use of corticosteroids.[109,110] This is an often-overlooked side effect of these drugs. Thus, calcium, vitamin D supplements, and bisphosphonates are recommended to minimize metabolic demineralization in all patients with IBD taking corticosteroids for longer than 3 months. Given the patient's family history (mother with osteoporosis) and her elevated risk of bone loss, alendronate 35 mg weekly with 1500 mg daily of calcium and 800 international units (IU) of vitamin D intake should be initiated.

Case 24-1, Question 8: A.C. is still responding well to oral prednisone; however, her blood glucose concentrations have ranged from 226 to 445 mg/dL (normal, 70–110 mg/dL). Her physician would like to try another modality for active treatment. What other drugs could be used for remission induction?

Previously, sulfasalazine was considered the drug of choice in UC exacerbation because of its demonstrated efficacy and reduced toxicity when compared with corticosteroids. However, controlled trials have shown that corticosteroids may act more promptly than does sulfasalazine alone for severe acute UC.[111] Sulfasalazine use has declined significantly because of the availability of better-tolerated 5-ASA formulations. Sulfasalazine use is often limited by its side effect profile including headache and nausea, as well as multiple daily dosing. In addition, as in the case of A.C., patients with a sulfa allergy should avoid sulfasalazine.

For patients with mildly active extensive UC, oral 5-ASA, also known as mesalamine, at a dose of 2 g/day is the preferred treatment for inducing remission.[112] Meta-analyses have shown that patients with moderately active UC may benefit from higher doses of

5-ASA at 4.8 g/day.[113] Single daily oral 5-ASA administration is found to be as effective as multiple daily doses and can be advantageous in increasing compliance.[113]

Patients with mildly active UC who are unable to reach remission with a 5-ASA should not be switched to an alternative 5-ASA formulation, because there is no therapeutic benefit between different formulations. Instead, they should be switched to corticosteroids for induction of remission.[75] In such patients requiring corticosteroid therapy, oral budesonide multimatrix system (MMX) 9 mg for 8 weeks would be preferred, and has been found to be more effective than continuing the oral 5-ASA. Budesonide is a long-acting corticosteroid with high first-pass metabolism and minimal side effects, and is therefore preferred over systemically active glucocorticoids in patients with mildly active UC.

For patients with moderately active UC, 5-ASA monotherapy for induction of remission is an option; however, it was not found to be effective in patients with severely active UC. Nonsystemic corticosteroids such as budesonide MMX are also preferred treatment options in patients with moderately active UC compared to systemic corticosteroids.

Infliximab, adalimumab, and golimumab are tumor necrosis factor (TNF) blockers that are effective for the induction of remission of moderate to severely active UC.[22] Patients with moderate to severely active UC, who fail TNF blockers, can be started on vedolizumab, which has a favorable safety profile and lower risk of infections compared to systemic immunosuppressive treatment options. Another treatment choice in patients who fail TNF blockers is tofacitinib, an orally administered small molecule that nonselectively inhibits the Janus kinase enzyme administered at a dose of 10 mg twice daily for 8 weeks. It is important to remember that infectious complications are more common in patients receiving tofacitinib including herpes zoster.[114]

In summary, oral 5-ASA compounds are considered first-line therapy for mildly active UC, with systemic corticosteroids reserved for more severely active UC or refractory disease. Because A.C. has improved symptomatically and is suffering significant adverse effects

from corticosteroid treatment, switching to oral mesalamine is a reasonable choice at this time.

Case 24-1, Question 9: A.C. feels much better and claims to be "back to normal." Her abdominal pain is gone, and she currently has two formed, nonbloody stools daily. Most of her laboratory parameters have returned to normal (ESR, 19 mm/hour; blood glucose, 95 mg/dL; WBC, 8300/μL). She is currently taking mesalamine 800 mg PO (orally) tid. What drug regimen should be used to maintain disease remission in A.C.?

5-ASA agents significantly reduce the incidence of relapse in patients with UC who are in remission.[105,115] As discussed previously, the anatomic site of disease is an important consideration in the selection of a 5-ASA preparation.[116] Data also suggest that, if tolerated, higher doses have higher rates of treatment success. In contrast, oral and topical corticosteroids do not prevent relapse of UC once remission has occurred.

Based on this information, A.C.'s mesalamine should be titrated to a total dose of 4.8 g in divided doses. If she experiences a relapse, a course of oral corticosteroids may be needed to reachieve remission. Prophylactic therapy should be continued indefinitely unless intolerable adverse effects develop.

Case 24-1, Question 10: A.C.'s mesalamine has been increased to 1200 mg tid for UC maintenance therapy. Several days after starting this higher dose of mesalamine, A.C. experienced anorexia, nausea, and epigastric pain. What is the possible cause of A.C.'s symptoms? How can they be minimized?

A.C. appears to be experiencing adverse effects of mesalamine. Although usually better tolerated than is sulfasalazine, unwanted adverse effects occur in 10% to 45% of patients. Most 5-ASA adverse reactions are dose related and tend to occur early during therapy.

Dose-related 5-ASA adverse effects can be minimized by initiating the patient on a low dosage (1–2 g/day) and gradually increasing the amount to tolerated therapeutic doses.[117] If dose-related reactions do

occur, the drug should be discontinued until the symptoms subside, and then it may be reinstituted at a lower dosage. A.C.'s symptoms are probably dose-related adverse reactions to mesalamine. The dosage should be decreased, or the drug temporarily withheld. If tolerated, the dosage can be increased slowly as necessary, or she can be switched to another agent to maintain disease remission, such as an immunomodulator.

Case 24-1, Question 11: A.C.'s dose of mesalamine was decreased to 800 mg tid. After 2 weeks, A.C. continued to have nausea, diarrhea, and headache severe enough to cause her to miss classes and call in sick from her part-time job. She lost 11.02 pounds (5 kg) (now 101.41 pounds [46 kg]) in the past week because of anorexia and nausea. What alternative therapies should be considered at this point?

For patients with previous moderate to severely active UC who are now in remission owing to induction with corticosteroids, such as A.C., or who have failed mesalamine or sulfasalazine, there is limited and conflicting evidence that thiopurines may provide clinical benefit.[118–120]

Methotrexate should not be used in patients with previous moderate to severely active UC because it has not been found to be therapeutically effective in maintaining remission after steroid induction.[80]

Patients who achieved remission with TNF blockers including infliximab, adalimumab, and golimumab, integrin inhibitor vedolizumab, or Janus kinase inhibitor tofacitinib should continue therapy for maintenance with the same pharmacologic agent.[22]

Because A.C. achieved remission with corticosteroids but is now unable to tolerate mesalamine, thiopurine therapy can be considered. In A.C., a reasonable choice would be azathioprine (AZA) 2.5 mg/kg/day. AZA is typically dosed in 50-mg increments; therefore A.C. should receive 100 to 150 mg/day of AZA. Clinicians should monitor WBC counts, liver function testing, and periodic assessment for any signs and symptoms of pancreatitis.

Case 24-1, Question 12: One year has passed since A.C. last had an acute attack of UC. She has been taking AZA 2.5 mg/kg/day. Today, she presented to her primary health care provider for her annual physical examination. She asked about receiving the yearly influenza vaccination as well as the pneumococcal vaccination she has been reading about online. Her primary care provider is unsure whether A.C. is a candidate for either vaccination. Should A.C. receive both vaccinations? What vaccinations, if any, is A.C. a candidate for?

Immunomodulators and biologic drugs are the mainstay of IBD treatment. However, some of the most important adverse effects are infectious complications. Some of these infections are preventable with immunizations.[121] Unfortunately, data exist that immunization strategies are significantly underutilized in the IBD population.[122] It is essential that patients with IBD receive age-appropriate vaccines, with additional vaccine considerations for patients initiated on immunosuppressive therapies. However, delaying certain live vaccinations may be necessary to ensure prompt administration of immunosuppressive therapy.[123] Nonlive vaccines are still administered according to recommendations from the Centers for Disease Control and Prevention.[124]

When considering live vaccine administration for patients with IBD, it is important to consider the patient's level of immunosuppression. Low-level immunosuppression includes patients receiving any of the following: daily dose of systemic corticosteroids for ≥14 days (prednisone 20 mg/day equivalent and within 3 months of stopping) or alternate-day corticosteroid therapy, methotrexate ≤0.4 mg/kg/week and within 3 months of stopping, AZA ≤3.0 mg/kg/day, or 6-mercaptopurine ≤1.5 mg/kg/day and within 3 months of stopping. Patients receiving TNF blockers are classified to have high-level immunosuppression. For patients receiving vedolizumab, live vaccines may be administered if the benefits outweigh the risks.[124]

All patients with IBD should undergo serologic testing for varicella, and if nonimmune, should be vaccinated against this virus. Because the varicella vaccine is a live vaccine, it should be avoided in

patients with high-dose immunosuppression; however, administration can be considered in patients on low-dose immunosuppression such as A.C., who is receiving AZA <3 mg/kg/day.[124]

Because patients with IBD who are immunosuppressed may have reactivation of hepatitis B infection, it is essential to test for hepatitis B before starting TNF blockers and vaccinate patients who are found to be nonimmune.[124]

Specifically, concerning A.C., she should receive the seasonal inactivated influenza and the 23-valent pneumococcal polysaccharide vaccines. Many patients with IBD would also be candidates for the human papilloma virus vaccine.[124]

CASE 24-2

Question 1: C.J. is a 30-year-old male who was well until 18 days ago when he experienced crampy right lower quadrant abdominal pain associated with an increased frequency of semiformed stools (4–5/day) that are streaked with fat. He has not taken any medications to prevent diarrhea. He describes the pain as "moderate," and it was episodic at first, exacerbated by meals, and relieved with defecation. He reports increased fatigue, which he attributes to recent anorexia and a 17.63-pound (8-kg) weight loss over the past 3 months. He denies any extraintestinal findings including arthralgias, changes in vision, or the appearance of skin rashes. He denies recent antibiotic use, travel outside the United States, or a personal or family history of food allergies or intolerance. He describes his general well-being as "poor."

Physical examination is normal, except for abdominal tenderness in the right lower quadrant when palpated. Vital signs include a temperature of 100.04 °F (37.8 °C), pulse of 100 beats/minute, and blood pressure of 135/75 mm Hg. He is 71 inches (180.34 cm) and weighs 176.37 pounds (80 kg).

Pertinent objective data are as follows:

Hct, 28%
Hgb, 9 g/dL
WBC count, 14.0 × 10^9/L
ESR, 60 mm/hour
CRP, 65 mg/L
Fecal calprotectin, 250 µg/g
Occult blood, positive
Stool culture/toxin findings negative for *Clostridioides difficile* and intestinal parasites
Crohn's Disease Activity Index score: 358 points

A barium enema shows an edematous ileocecal valve and a terminal ileum that has a nodular irregularity of the mucosa. Follow-up ileocolonoscopy reveals a cobblestone-appearing terminal ileum with areas of normal tissue separated by diseased mucosa. Results of sigmoidoscopy and rectal biopsy are negative. Which of C.J.'s signs, symptoms, and laboratory data are consistent with CD? What is the pathophysiologic basis for his clinical presentation?

C.J. presents with the classic symptom triad of abdominal pain, diarrhea, and fatigue, in addition to weight loss.[28] His abdominal pain is secondary to inflammation in the ileocecal area. Diarrhea is common, and in contrast to UC, the stools are usually partly formed, without overt rectal bleeding, although possible with diseased sigmoid or rectal tissue. For colonic disease, the quality and quantity of diarrhea may be similar to that of UC. Significant ileal inflammation can result in bile malabsorption, resulting in fatty streaks called *steatorrhea*.[88] Weight loss may be pronounced in patients with long-standing CD because of anorexia and malabsorption. In addition, vitamin deficiencies are common given the extent of intestinal involvement.[88] The patient interview should include questions related to quality of life, although limited by subjectivity, because they contribute to the Crohn's Disease Activity Index score.[27] In addition, differential diagnoses should be excluded, such as traveler's diarrhea, infection risk, and food intolerance.

Rectal bleeding in CD is less common than in UC, but it may occur with colonic involvement. It can be detected using an occult blood test, with a positive result indicating the presence of blood. Slow blood loss over time can result in anemia, but altered iron metabolism in the presence of inflammation is another common cause.[125]

C.J.'s inflammatory markers demonstrate that, similar to UC, CD has systemic effects. Elevated WBC, ESR, CRP, and fecal calprotectin are common, and studies are ongoing to determine how they might be used to diagnose the disease, assess severity, and monitor response to therapy. For example, fecal calprotectin is a noninvasive tool that can differentiate IBD from other causes, including IBS, and may correlate well with endoscopic findings to assess mucosal healing.[28,126]

Most patients with CD have recurrent, symptomatic episodes of pain and diarrhea with progressively shorter asymptomatic periods. Although the clinical course is progressive, 10% of patients will remain asymptomatic after a few acute episodes.[126] Other patients may only manifest a slight fever for years until a late complication of the disease, such as fistula formation, develops. Alternatively, CD may be rapidly progressive, in the case of fulminant disease.

CASE 24-2, QUESTION 2: What agents can be used to induce remission of C.J.'s CD?

Based on C.J.'s subjective and objective findings, including a Crohn's Disease Activity Index score between 220 and 450, he likely has moderate-to-severe CD for which budesonide and sulfasalazine are not indicated.[28,32] Immunomodulators including thiopurines and methotrexate are also inappropriate at this time given their delayed onset of action and limited utility for induction.[28,51–53] C.J. has no complications that might warrant the use of infliximab or another TNF blocker in favor of other therapies. Considerations for therapy selection include safety, effectiveness, cost, and patient preference.

Corticosteroids are widely used therapeutic agents for the treatment of active, symptomatic CD.[127,128] They may be recommended for short-term, symptomatic relief during an active flare, but are not recommended for maintenance therapy because they cannot promote mucosal healing, and they have well-known adverse effects associated with long-term use (see Table 24-5).[128–130] There are no head-to-head trials to compare effective steroid regimens, but they generally include tapering prednisone, prednisolone, or methylprednisolone from doses not to exceed 40 to 60 mg prednisone equivalents per day.[129] Studies suggest that oral budesonide is about as equally effective as conventional steroids for mild-to-moderate IBD flares localized to the ileum and ascending colon.[47–49,130] Budesonide has a pH-dependent controlled ileal release formulation that acts locally and topically to reduce inflammation.[47–49] This formulation is preferred to conventional

steroids in mild cases because of reduced systemic exposure and adverse effects, but is not appropriate for C.J. given his disease severity.

Although used extensively in the past for mild-to-moderate CD, trial data and expert opinion have limited the role of 5-ASA to mild active colonic CD.[28,75] Oral mesalamine has not consistently demonstrated benefit over placebo, but sulfasalazine may benefit individuals with mild-to-moderate colonic CD who require symptomatic relief.[28] Sulfapyridine is the component of sulfasalazine that helps deliver 5-ASA to the colon; therefore, it remains largely ineffective for CD in other intestinal areas.[28] C.J. is not an appropriate candidate for sulfasalazine based on disease severity and his intestinal location of disease.

The immunomodulators AZA, 6-mercaptopurine (6-MP), and methotrexate have delayed clinical benefit, up to 12 weeks or more, which minimizes their utility for induction therapy. However, biologic agents are considerations for induction.[28] Infliximab and adalimumab are thought to be superior to certolizumab pegol for remission induction.[131–133] Uniquely, certolizumab pegol contains only the antibody receptor for TNF-α bound to polyethylene glycol (PEG) to increase its duration in the body,[63] but the impact on clinical outcomes is unknown. Studies suggest a roughly equivalent response between adalimumab and infliximab[134] but large, head-to-head studies including certolizumab pegol are lacking.[133] Infliximab has the most data to support its use for fistulizing disease,[135] but guidelines state that adalimumab and certolizumab pegol may still be considered to treat perianal fistulas.[128] Despite the high relative efficacy of TNF blockers, nearly a third of treated individuals are primary nonresponders, meaning they receive no benefit from the drug. Over time, about half of the primary responders become secondary nonresponders within the first year, requiring dose escalation or therapy change because of the development of antidrug antibodies.[35,36] Because immunomodulator adjunct therapy can reduce the development of antidrug antibodies, these agents can be used in combination, regardless of prior failed therapy to immunomodulators.[136,137] Data are developing regarding combined

use, and risks should be evaluated before choosing combined therapy. Infliximab is only administered IV, so one potential advantage of adalimumab or certolizumab pegol is the ability to self-administer them subcutaneously at home. Infliximab and adalimumab have approved biosimilars available, whereas a biosimilar for certolizumab pegol is currently under development.

Natalizumab may be beneficial for induction and maintenance of remission for moderate-to-severe CD, but at the increased risk of developing progressive multifocal leukoencephalopathy (PML), a potentially fatal infection of the nervous system.[70,138] For individuals with positive John Cunningham virus antibody, an estimated 1 in 100 will develop the disease; thus, testing is required before therapy initiation and at least every 6 months during continued use to ensure safety.[70,139] Furthermore, patients are required to be enrolled in a mandatory patient registry program (TOUCH, TYSABRI Outreach: Unified Commitment to Health) to receive the drug and should avoid concomitant immunosuppressive therapies.[70] As a result, natalizumab has fallen out of favor compared to alternative therapies.[140] In 2014, vedolizumab was approved for inducing and maintaining remission of moderate-to- severe UC and CD in patients who have failed TNF-α therapy or demonstrated corticosteroid dependence.[71] Vedolizumab differs from natalizumab because it is gut-selective, thereby reducing the risk of PML, for which no cases were observed in clinical trials.[141,142] Although gut-selective, some studies still suggest improvement in extraintestinal manifestations.[143,144] Vedolizumab is known for its relatively favorable safety profile without a black box warning for increased risk of infection or malignancy.[71,140] Anti-integrin therapy works better among TNF blocker–naive individuals,[140–142] but guidelines do not require failed TNF blocker therapy before considering their use.[28,32]

Ustekinumab is typically reserved for moderate-to-severe CD in patients who have failed or were intolerant to prior therapies, regardless of prior TNF blocker use.[28,72,145] However, it has emerged as a first-line treatment option for moderate-to-severe CD owing to its relatively low immunogenicity and high safety profile compared to other biologics.[146] Data are limited regarding its comparison to

alternative therapies, particularly its ability to reduce surgical necessity or hospitalization.[146] Similar to anti-integrin agents, ustekinumab maintenance therapy is only approved following induction with the same agent.[72] Clinical benefit is expected within 3 weeks of initiation.[145]

Case 24-2, Question 3: C.J. and his provider chose corticosteroid therapy to induce remission, because of cost, route of administration, and effectiveness. After 3 weeks of using prednisone 40 mg daily, C.J. experiences fewer symptoms of CD. He passes one to two well-formed stools daily, has increased appetite and weight, decreased abdominal pain and tenderness, and normal body temperatures. Despite attempts to taper the dose, C.J. states he is unable to tolerate a dose decrease. What therapies are effective for maintaining remission?

Once prednisone has induced remission of active symptomatic CD, attempts should be made to taper the drug over a duration long enough for maintenance therapy to take effect, if needed.[129] Studies suggest that corticosteroids do not impact mucosal healing and are not effective in maintaining remission.[28] Up to one-third of patients with CD require chronic administration of corticosteroids to prevent recurrence of symptoms (termed steroid-dependent CD).[126] Because C.J. has not tolerated tapering and long-term high-dose treatment is unsafe, alternative maintenance therapy is warranted.

With the advent of biologics, some experts advocate for a "top-down" approach, in which biologic therapy is introduced upfront for high-risk patients with moderate-to-severe CD.[147] TNF blockers may be appropriate at this time. Typically, anti-integrin and anti-interleukin therapies are reserved for maintenance therapy if used for induction.[70–72] In this case, a conventional approach is also acceptable, particularly given that the cost of thiopurines and methotrexate is often favorable. Guidelines recommend considering thiopurines for steroid-dependent disease and maintenance in relapsing cases, regardless of anatomic site or severity.[28] Methotrexate is another conventional option, typically reserved where other treatments have failed (see Table 24-5). C.J. can take 6-MP 120 mg (1.5 mg/kg/day) or AZA 200 mg (2.5 mg/kg/day). He will

continue prednisone upon thiopurine initiation because it may take several weeks to take effect, but the steroid will soon be tapered. C.J.'s WBC counts should be monitored regularly, and he should be counseled regarding the signs and symptoms of severe infection and pancreatitis (see Table 24-4).

Case 24-2, Question 4: Six weeks into initiating AZA and tapering prednisone (currently, 10 mg/day), C.J. returns to the clinic for routine laboratory monitoring. His WBC count is 1800/μL with an absolute neutrophil count of 1100/μL. He is afebrile. His physical examination finding is negative for any sign of infection. This is in keeping with the current person-first terminology.

AZA is a prodrug that is converted to the active moiety, 6-MP, in the liver, which is then metabolized by xanthine oxidase, hypoxanthine- guanine phosphoribosyltransferase, or thiopurine-S-methyltransferase (TPMT).[51,137,148] Genetic polymorphisms determine the extent of TPMT activity, which varies by ethnicity.[148] An estimated 90% of adults have normal enzymatic activity, but those with reduced TPMT activity are predisposed to myelosuppression because of drug accumulation. Pharmacogenomic testing to assess TPMT activity may inform the appropriate use of thiopurines to minimize the incidence of bone marrow suppression.[137,148]

For patients such as C.J. who experience neutropenia from AZA therapy, the primary treatment is to discontinue use and monitor for signs and symptoms of infection. Upon discontinuation, the WBC count should be monitored regularly until it exceeds 3000/μL. This may take several days to weeks. In extreme cases, the use of granulocyte colony-stimulating factor may be considered. The clinician should avoid initiating another thiopurine in the future, including 6-MP.

Case 24-2, Question 5: C.J.'s leukocyte count returned to normal after 3 weeks. Unfortunately, he experienced a flare of his CD symptoms, specifically, an increase in diarrhea and abdominal pain that C.J. has noted during the past 2 weeks. He states that he and his wife are preparing to start a family soon, and he would like to control his symptoms before new stressors confound his symptoms. He lives in a rural area, far from an infusion clinic, so he prefers the

autonomy of home medication use. What other agents should be considered at this time?

Methotrexate induces and maintains remission in patients with refractory disease and can be used in the case of failed or intolerable thiopurine use. Clinical improvement or reduction in corticosteroid doses have been observed with 15 mg/week subcutaneous methotrexate or 25 mg/week of intramuscular methotrexate, but its effect on endoscopic healing has not been assessed.[149] Folic acid is required in combination with methotrexate because of its inhibition of dihydrofolate reductase.[53,54] Reasons for methotrexate discontinuation include GI toxicity, neutropenia, and hepatotoxicity. For C.J., however, this option is not appropriate because methotrexate is teratogenic. Therefore, pregnancy should be avoided when either partner is using methotrexate, up to 3 months following discontinuation for males, and after completion of at least one ovulatory cycle following discontinuation for females.[53,54,150]

C.J. has been experiencing new symptoms for 2 weeks, so it would be appropriate to reconsider induction at this time, followed by maintenance. Natalizumab is not preferred based on safety, convenience, and route of administration (see Table 24-5). Infliximab and vedolizumab are also not self-administered at home. Ustekinumab is administered IV but only for the induction dose, followed by subcutaneous injections every 8 weeks thereafter. Adalimumab and certolizumab pegol are self-administered every 2 or 4 weeks, respectively, following induction treatment. TNF blockers have boxed warnings for increased risk of infection and malignancy, whereas ustekinumab has similar but less pronounced risks, in addition to a rare risk for reversible posterior leukoencephalopathy syndrome.

C.J. and his provider learn that adalimumab is the preferred agent on his insurance formulary, and C.J. does not meet prior authorization criteria for alternative therapies. He will start adalimumab 160 mg subcutaneously (four 40-mg injections for 1 day or two 40-mg injections for 2 days) followed by 80 mg in 2 weeks.

Two weeks after the second dose, he will initiate a 40-mg maintenance injection every other week. C.J. must test negative for hepatitis B, tuberculosis, and all other active infections before starting treatment. Periodic tuberculosis screenings must also return negative results. He will monitor for signs and symptoms of hypersensitivity, and infection throughout its use.

Case 24-2, Question 6: C.J. has developed an enterocutaneous fistula with his latest disease exacerbation, and nothing is helping him achieve remission. Does this new development require C.J. to change his therapy?

Adalimumab may be effective for treating perianal fistulas, but infliximab is now firmly established as an integral treatment for fistulizing disease.[28] Hypersensitivity reactions may be severe or delayed, but typically include urticaria, dyspnea, and/or hypotension within 2 hours of infusion.[65–69] Pretreatment with diphenhydramine, acetaminophen, and/or corticosteroids is common to mitigate these reactions.

Like all TNF blockers, infliximab should be avoided in patients with active infection. Screening and/or monitoring for tuberculosis and hepatitis are recommended before and throughout treatment. Current data concerning a link between TNF-α blocker use and malignancy are conflicting.[35] To date, the data suggest a small risk of developing lymphoma when using TNF-α blockers, but the benefits of increased quality of life may outweigh the risk.

Case 24-2, Question 7: C.J. was initiated on infliximab 400 mg IV every 8 weeks, and it was successful in keeping him symptom free. However, after 2 years of remission, C.J. is hospitalized for an acute exacerbation of right lower quadrant pain associated with abdominal distension, lack of bowel movements, and vomiting during the past 24 hours. Radiographic studies indicate partial small bowel obstruction at the terminal ileum. Is surgery indicated at this time?

Owing to the natural progression of disease, medical therapy may be inadequate. Most patients with CD require at least one surgical resection throughout the course of disease.[151] In contrast to UC,

surgical removal of the involved bowel in CD is not a definitive form of therapy, as indicated by the risk of recurrence even after extensive resection.[126] Depending on the amount and site of the bowel removed during surgery, specific malabsorption syndromes can occur (eg, vitamin B_{12} malabsorption with removal of the terminal ileum). If an ileostomy is necessary, the patient may need psychological support. Surgery is indicated only for specific complications that are unresponsive to medical therapy, and it should be avoided if possible.

IRRITABLE BOWEL SYNDROME

IBS is one of the most highly prevalent disorders of the gut–brain interaction, in which a patient has recurrent abdominal pain associated with defecation, bloating, and disordered bowel habits.[152]

The prevalence of IBS in the United States is 10% to 20%, with a higher incidence in patients younger than 50 years.[153] Patients with IBS have a poor quality of life, and there are significant gender differences and variability among IBS subtypes.[153,154] Compared to males, females are almost three times more likely to have IBS, have a higher incidence of irritable bowel syndrome with constipation (IBS-C), and report more fatigue, depression, anxiety, and a lower quality of life.[154,155] In contrast, males with IBS report a higher incidence of irritable bowel syndrome with diarrhea (IBS-D).[155,156] Patients with IBS-C are more likely to report avoiding sex, difficulty concentrating, and feeling self-conscious compared to those with IBS-D. Patients with IBS-D more frequently report avoiding places without bathrooms, having difficulty making plans, and being reluctant to travel, compared to those with IBS-C.[157] The U.S. health care burden exceeds $20 billion for IBS management.[158] Despite patients' frequent use of health care services and decrease in their quality of life, IBS is non–life-threatening with a good prognosis.[159]

Pathophysiology

The pathophysiology of IBS remains complex and poorly understood.[159] There are multiple influencing factors, including an interaction between the brain–gut axis, psychosocial factors, visceral hypersensitivity, GI dysmotility, altered microbiota, and immune dysregulation. Other factors include intestinal permeability, postinfectious low-grade inflammation, bacterial overgrowth, and food sensitivity.[152,159,160]

The brain and gut communicate with each other using complex pathways between the enteric nervous system, the autonomic nervous system, the hypothalamus–pituitary–adrenal axis, and the central nervous system.[161] This brain–gut communication affects GI motility, secretion, and immune regulation, which influences food intake, digestion, gut sensation, and bowel movement. In IBS, this communication between the brain and gut is disrupted.[159] For example, genetics, culture, and the environment (trauma, infection, parental behaviors) influence psychosocial development. Psychosocial development includes coping skills, personality traits, psychological state, cognition, and social support. Genetics, culture, and environment also influence gut physiology (motility, sensation, altered microflora, immune dysfunction, inflammation, and the effect of food/diet).[162] Scientists believe that IBS results from the dysfunctional interactions between psychosocial development and physiologic factors.[162]

Visceral hypersensitivity is a mechanism for abdominal pain in IBS. Studies show that patients with IBS have dysregulation with activation of certain brain regions affecting pain during rectal distension.[159,163]

Experts suggest that the interstitial cells of Cajal (ICC) produce, propagate, and regulate waves affecting GI motility, causing high-amplitude propagating contractions resulting in an urge to defecate, abdominal cramps, and pain. Having less ICC results in fewer contractions, leading to constipation in IBS-C. Alternatively, with more ICC, there are more contractions, leading to diarrhea in IBS-D.[152,160]

The gut microbiota play a major role in digestion, homeostasis, and immunity, but early life stresses alter its composition.[161] Patients with altered microbiota can develop immune dysregulation, mucosal membrane permeability, altered tight cell junction, activated mast cells, increased inflammatory cytokine release, and inflammation leading to visceral hypersensitivity.[162] Patients who had an acute gastroenteritis, with a large bacterial load, lengthy disease duration, psychosocial condition, high life stress, sexual or physical abuse history, and/or poor coping skills can develop severe postinfectious IBS with poor outcomes.[162]

Clinical Presentation

The symptoms of IBS include abdominal bloating, distension, recurrent abdominal pain associated with defecation, and disordered bowel habits (ie, constipation, diarrhea, or both). Notably, these symptoms cannot be explained by structural or biochemical abnormalities.[154] Stress and food aggravate the symptoms, which vary in frequency and severity, resulting in a chronic debilitating relapsing and remitting disorder.[164] Patients may also commonly report extra-GI symptoms of headache, dysmenorrhea, dyspareunia, and fatigue. In addition, patients commonly present with comorbidities such as stress, anxiety, depression, dyspepsia, interstitial cystitis, and fibromyalgia.[162,164]

Diagnosis

There are no objective diagnostic tests for IBS, and the condition is diagnosed based on clinical presentation and exclusion of other causes as listed in **Table 24-7**.[154,165,166] The Rome IV criteria is used for IBS diagnosis, and is made when the patient presents with recurrent abdominal pain, at least 1 day per week in the past 3 months, associated with any two or more of the following:

Table 24-7

Differential Diagnoses to Consider Before Making an Irritable Bowel Syndrome Diagnosis

Inflammatory bowel disease
Food intolerance or sensitivity
Small intestinal bacterial overgrowth
Bile acid diarrhea
Pancreatic exocrine deficiency
Medication side effects
Functional diarrhea
Colon cancer
Chronic parasitic infection
Microscopic colitis
Thyroid disease
Celiac disease

1. related to defecation, and/or
2. associated with a change in frequency of stool, and/or
3. associated with a change in form (appearance) of the stool.

IBS is diagnosed if any of the abovementioned three criteria is fulfilled for the past 3 months with symptom onset at least 6 months before diagnosis.[154]

The Bristol Stool Form Scale, **Figure 24-3**, is used as an aid to help patients describe their stool form (eg, hard/lumpy or loose/watery stool) without the use of laxatives or antidiarrheal medications.[154,167] Because there are no organic or structural observations in patients with IBS, a colonoscopy is not generally required, and reserved only for patients older than 50 years, or those who present with alarm symptoms, which include[154,158]:

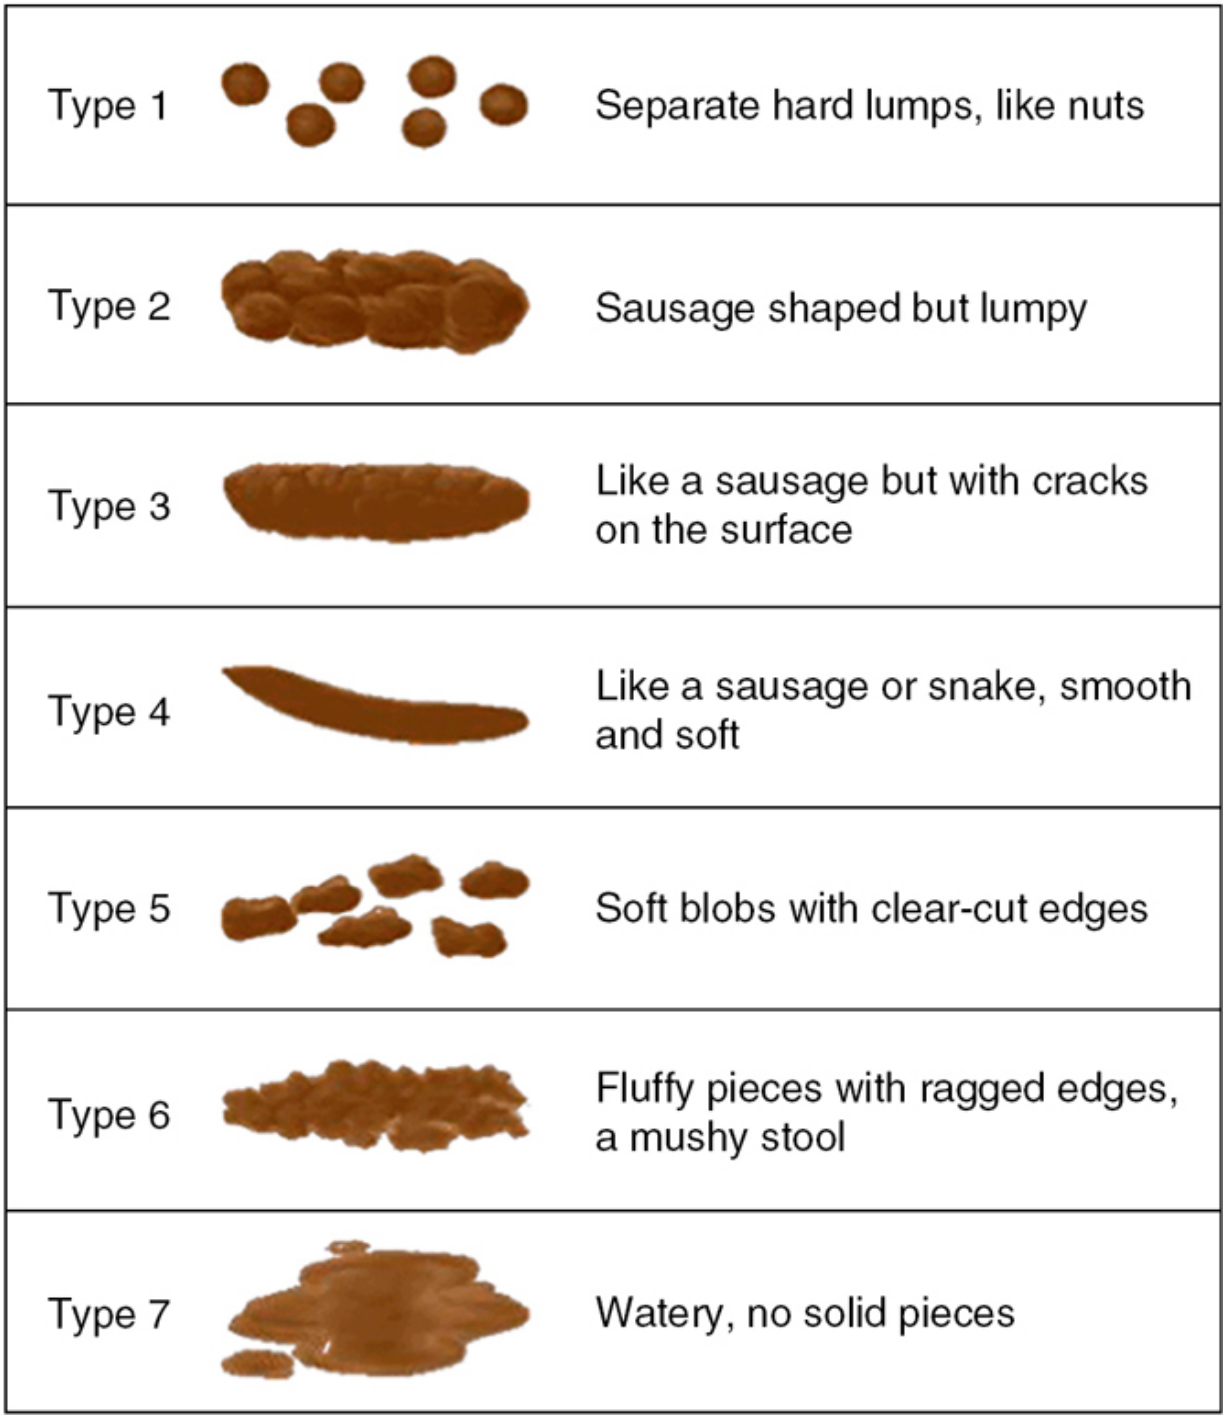

Figure 24-3 Bristol Stool Form Scale. (Reprinted with permission from the Rome Foundation. All rights reserved.)

- Abdominal pain and cramping not relieved by bowel movement
- Nocturnal symptoms (abdominal pain and cramping, which awakes the sufferer from sleep)

- Palpable abdominal mass
- Fatigue
- GI or rectal bleeding
- Iron-deficient anemia
- Weight loss (significant, unintentional, and unexplained)
- Fever
- Night sweats
- Age of onset older than 50 years
- Family history of IBD, colorectal cancer, or organic GI disease
- Symptoms that persist when fasting
- Low fecal osmotic gap

Once diagnosed, IBS is differentiated into subtypes based on the predominant symptom: IBS-C, IBS-D, irritable bowel syndrome mixed (IBS-M), or unclassified irritable bowel syndrome (IBS-U) defined in **Table 24-8**.[154]

Table 24-8
Diagnostic Criteria for Irritable Bowel Subtypes

Subtypes	Diagnostic Criteria
IBS-C	>25% of bowel movements with Bristol Stool Form types 1, 2 and <25% of bowel movements with Bristol Stool Form types 6, 7
IBS-D	>25% of bowel movements with Bristol Stool Form types 6, 7 and <25% of bowel movements with Bristol Stool Form types 1, 2
IBS-M	>25% of bowel movements with Bristol Stool Form types 1, 2 and >25% of bowel movements with Bristol Stool Form types 6, 7
IBS-U	Patients meet diagnostic criteria for IBS, but their bowel habits cannot be accurately categorized in any of the abovementioned subtypes.

IBS-C, irritable bowel syndrome with constipation; IBS-D, irritable bowel syndrome with diarrhea; IBS-M, mixed irritable bowel syndrome; IBS-U, unsubtyped irritable bowel syndrome.

Overview of Treatment

Treatment should target the predominant symptom such as constipation, diarrhea, bloating, or abdominal pain. There are currently no available agents that treat the entire spectrum of IBS symptoms, so multiple interventions may be warranted. Nonpharmacologic interventions target stress relief and lifestyle modifications. These include reassuring the patient, creating a strong physician–patient relationship, improving sleep habits, increasing exercise, and subscribing to a low-FODMAP diet (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols).[154] Soluble dietary fibers, such as psyllium, act as stool bulking agents and improve stool consistency, but there are few studies to evaluate their role in IBS-D.[158] Osmotic laxatives and stool softeners treat constipation, although not specifically U.S. Food and Drug Administration (FDA) approved for IBS-C. According to the American College of Gastroenterology, tricyclic antidepressants are recommended for abdominal pain and IBS global symptoms, but antispasmodics are not recommended.[168] No medications are FDA approved to treat IBS-M or IBS-U.[169] Clinicians can use the suggested treatment algorithm depicted in **Figure 24-4** for IBS management.[158,164,165,168,170,171]

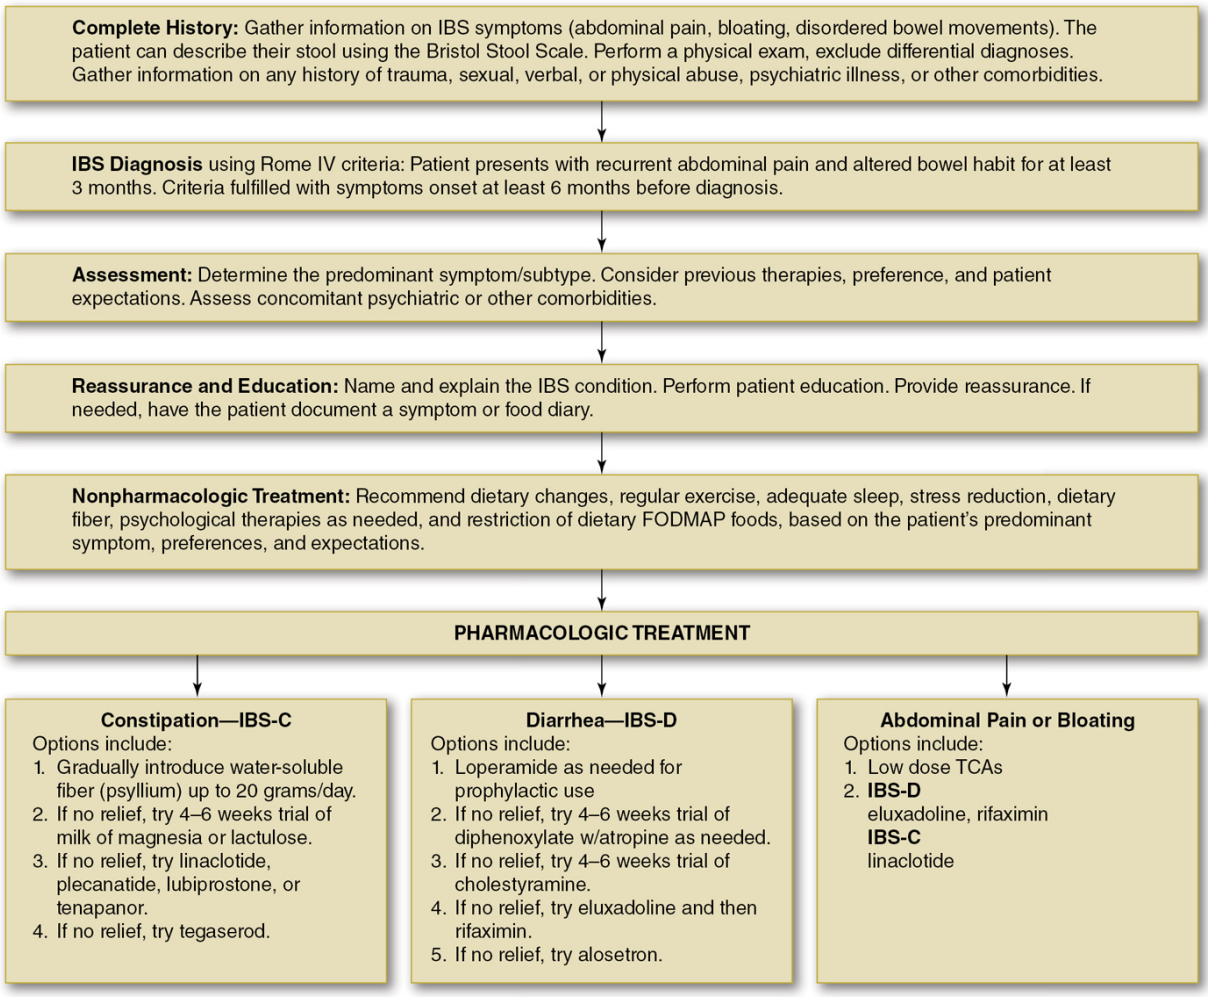

Figure 24-4 Irritable bowel syndrome management algorithm. FODMAP, fermentable oligosaccharides, disaccharides, monosaccharides, and polyols; IBS, irritable bowel syndrome; IBS-C, irritable bowel syndrome with constipation; IBS-D, irritable bowel syndrome with diarrhea; TCA, tricylic antidepressants. PATIENT EDUCATION

CASE 24-3

QUESTION 1: V.H. is a 28-year-old female who presents with severe abdominal pain (rated 7 on a scale of 0–10) and bloating with the passage of hard, pellet-like stools every 3 days for the past 7 months. She notices that an "attack" normally occurs after a large meal. Her past medical history is significant for

generalized anxiety disorder for which she takes buspirone. She denies using alcohol, tobacco, or illicit drugs.

What subjective data in the case is consistent with IBS?

V.H. presents with recurrent abdominal pain at least 1 day per week in the past 3 months that is associated with defecation and constipation. The symptoms started at least 6 months ago, consistent with the diagnosis of IBS. Although common in IBS, bloating and symptoms exacerbated by meals are not criteria for diagnosis.

CASE 24-3, QUESTION 2: V.H. is concerned that her symptoms are indicative of cancer. How should the clinician respond to V.H.'s concerns?

Many patients are fearful that their symptoms are indicative of cancer. Clinicians should reassure V.H. that the diagnosis is accurate, benign, and treatable.[154] An effective physician–patient relationship is important to maintain patient satisfaction, adherence to therapy, and symptom reduction.[172] Involving patients at the earliest stages in their treatment plan is vital for patient acceptance to avoid "doctor shopping," where patients seek second opinions from other providers. Initial interventions may be multidisciplinary to provide reassurance and provide interactive patient education.

CASE 24-3, QUESTION 3: After educating V.H. on IBS, she seems less worried and suggests making lifestyle modifications to "cure" IBS. What evidence-based, nonpharmacologic recommendations can be provided?

NONPHARMACOLOGIC: LIFESTYLE MODIFICATIONS

Many patients believe their symptoms are diet related.[165] The mechanisms by which food can worsen IBS symptoms include gastrocolic reflex, food maldigestion or malabsorption, food allergy, and visceral hypersensitivity.[173] More than 40% of patients with IBS have lactose intolerance and experience pain, bloating, and diarrhea after ingesting milk-based products. Some experts recommend

avoiding lactose, whether intolerant or not.[158] However, exclusion diets are generally not recommended because most patients with IBS have difficulty complying or will not achieve significant symptomatic relief.[165] Current experts recommend against following a gluten-free diet, because trials did not demonstrate a positive impact on IBS symptoms.[165]

Patients with IBS can have poor absorption of FODMAP diets because fermentation by gut bacteria produces gas, luminal distension, bloating, and worsening abdominal pain.[173] Some researchers believe a low-FODMAP diet can have detrimental effects on the normal gut microbiota, and thus only recommend it for symptomatic patients.[174] However, the American College of Gastroenterology recommends a low-FODMAP diet for overall symptom improvement and pain reduction in patients with IBS.[165]

Prebiotics and synbiotics lack efficacy in treating IBS symptoms, and probiotic use is now restricted to clinical trials only.[165,175] Patients with IBS-C may benefit from increased consumption of soluble fiber up to 20 g daily. Psyllium significantly improved IBS symptoms, stool viscosity, and frequency in trials.[165,176] However, large doses of fiber can lead to abdominal gas and bloating, so patients should introduce fiber gradually. Insoluble fiber (wheat bran) is not effective and can worsen symptoms of bloating, cramping, or flatulence.[177] Exercise improves physical and mental health, but needs rigorous studies as a treatment choice.[165]

V.H. should be reminded that IBS has no cure. She should be encouraged to keep a food diary to identify any food intolerances and avoid those foods. Whether she is lactose intolerant or not, she can omit dairy products. She should avoid prebiotics, synbiotics, probiotics, insoluble fiber, and gluten-free diets, which are not evidence based, and can increase unnecessary cost. To reduce bloating and gas, she should eat small, frequent meals, gradually introduce soluble fiber (eg, psyllium), and follow a low-FODMAP diet. She should incorporate exercise and adequate sleep to bolster physical and mental health.

Case 24-3, Question 4: Several months have passed since V.H. was first diagnosed with IBS-C. She still reports of some constipation and abdominal pain. She wants to try other nonpharmacologic therapies. What other nonpharmacologic options are available?

PSYCHOLOGICAL THERAPIES

Psychological disorders are present in a sizable number of patients with IBS. Treating comorbid psychological disorders and identifying overlooked sexual abuse or posttraumatic stress disorder are important components to successfully treat IBS.[178] Some patients exhibit a phenomenon known as *somatization*, which is a tendency to experience and communicate somatic distress in response to psychosocial stress. Patients with IBS should be encouraged to seek health care for their condition.[179] Educational sessions and psychological techniques are thought to decrease the risk of developing somatization, but data are limited.[180]

In a recent meta-analysis, cognitive behavioral therapy, relaxation therapy, multicomponent psychological therapy, hypnotherapy, and dynamic psychotherapy have all been shown to reduce overall symptom burden in patients with IBS.[181] For patients with psychiatric comorbidities, poor social support, traumatic life events, and dysfunctional relationships, clinicians should consider psychotherapy very early in IBS management.[181] An expert consensus recommends psychological therapies for patients who have not responded to first- or second-line treatments after 3 to 6 months, or for those with a significant association between stress and IBS symptoms.[182]

Case 24-3, Question 5: V.H. has since changed her diet and had therapeutic trials of several over-the-counter agents that were either poorly tolerated or lacked effectiveness. What other options are available for treating V.H.'s IBS-C?

Pharmacotherapy for Irritable Bowel Syndrome With Constipation

For patients with IBS-C in whom soluble fiber fails, osmotic laxatives

(e.g, milk of magnesia, lactulose, PEG without electrolytes), or stool softeners may be tried. However, the ACG recommends against the use of PEG products to relieve global IBS symptoms in those with IBS-C.[168,183] Few well-designed trials assess the use of any laxative for IBS. Laxatives are usually well tolerated and provide constipation relief, but may cause bloating, diarrhea, taste disturbances, and hypermagnesemia (especially in patients with renal impairment). Thus, other treatments will be needed in many patients.

The agents lubiprostone, linaclotide, plecanatide, and tenapanor are indicated for the treatment of IBS-C, and they all share the same contraindication of avoiding in patients with mechanical GI obstructions.[184–187] Although lubiprostone is indicated only for adults age 18 years and older, all the other agents have additional documented contraindications for avoiding in children younger than 6 years. In addition, clinicians should avoid use of all four agents in children ages 6 to 17 years because of death from dehydration in younger juvenile mice.[184–187]

LUBIPROSTONE (AMITIZA®)

Lubiprostone is a GI chloride channel activator that enhances chloride influx into the intestinal lumen, resulting in increased intestinal fluid secretion and small and large bowel intestinal transit.[184] The FDA approved lubiprostone for females older than 18 years with IBS-C, at a dose of 8 µg orally twice daily with food to reduce the adverse effects of nausea and vomiting.[184]

Two studies found that lubiprostone was moderately effective in improving patient perception of constipation.[188,189] Very few males with IBS-C were enrolled in the clinical trials with lubiprostone to draw any conclusions about its effectiveness in males. Lubiprostone is associated with teratogenic effects in animals, so females of childbearing age need a negative pregnancy test result before beginning therapy and must use contraception during therapy.[184] Lubiprostone is more expensive than are traditional laxatives, and should be reserved for patients with IBS-C who have failed cheaper alternatives. Acute-onset dyspnea, syncope, and hypotension may

occur, but typically resolve within a few hours or upon discontinuation.[184] Monitor patients for dyspnea, hypotension, and syncope, especially if patients are taking concomitant antihypertensives or high doses of lubiprostone.[184]

LINACLOTIDE (LINZESS®)

Linaclotide is a guanylate cyclase-C agonist and, together with its active metabolite, acts locally on the luminal surface of the intestinal epithelium to stimulate and increase chloride and bicarbonate secretions into the intestinal lumen, increase GI motility, decrease pain, and improve stool consistency. Linaclotide is approved for adult male and female patients with IBS-C at an oral dose of 290 µg daily taken 30 minutes before breakfast to reduce the side effects of diarrhea, abdominal pain, and gas.[185]

Patients receiving linaclotide in trials reported statistically significant improvements in abdominal pain, discomfort, bloating, bowel straining, constipation, and stool consistency.[190,191] Upon discontinuation, abdominal pain returned and bowel movements decreased to levels similar to the placebo group, but there was no rebound effect noted.[190,191] The main side effects of linaclotide are diarrhea, abdominal pain, and flatulence.[185]

PLECANATIDE (TRULANCE®)

Plecanatide is a guanylate cyclase-C agonist with a mechanism of action similar to that of linaclotide, but whereas linaclotide acts throughout the entire GI tract, plecanatide affects only the proximal small bowel.[192] Plecanatide is similar to endogenous uroguanylin, except for a single amino acid substitution for greater binding affinity, and activates guanylate cyclase-C receptors in a pH-sensitive manner in the small intestine to stimulate fluid secretion, maintain stool consistency, and decrease visceral pain. Experts believe that this difference results in less diarrhea with plecanatide compared to that with linaclotide.[192] Plecanatide is approved for adult male and female patients older than 18 years with IBS-C at an oral dose of 3 mg daily without regard to food.[186]

Patients taking plecanatide in clinical trials demonstrated significant improvements in bowel movements, stool consistency, pain reduction, satisfaction, and a desire to continue therapy, with a low incidence of diarrhea.[193,194]

TENAPANOR (IBSRELA®)

Tenapanor inhibits the sodium/hydrogen exchanger isoform 3 on the apical enterocytes of the small intestine and colon, reducing sodium absorption from the colon and intestines. This inhibition results in increased intestinal lumen secretions and accelerated gut transit time, resulting in a softer stool consistency and normalized bowel movement frequency.[195] Tenapanor is FDA approved for treating IBS-C in adult male and female patients older than 18 years at a dose of 50 mg orally twice daily to be taken immediately before breakfast and dinner.[187]

Patients on tenapanor for IBS-C had significant improvement in abdominal and global IBS symptoms in clinical trials.[196] Diarrhea was the most reported adverse effect. Clinicians and patients should monitor for signs and symptoms of diarrhea, which can lead to dehydration. Patients with renal impairment should be carefully monitored because they may be at greater risk for adverse reactions including diarrhea and hyperkalemia, requiring subsequent hospitalizations.[187]

In the absence of head-to-head trials, a meta-analysis was designed to compare the efficacy of linaclotide, lubiprostone, tenapanor, and plecanatide for treating IBS-C.[197] Study results show that all therapies were efficacious and superior to placebo. Linaclotide was ranked highest in efficacy by achieving significant abdominal pain reduction and complete spontaneous bowel movements. A complete spontaneous bowel movement occurs without the use of rescue medication and the sensation of complete evacuation. Tenapanor was ranked first for decreasing bloating, and plecanatide was ranked first for safety. Diarrhea was common among all therapies except lubiprostone, with which nausea was more common.[197] Current guidelines strongly recommend linaclotide

because of high certainty of evidence, but cautions its use in patients who want to avoid diarrhea and high drug cost. Plecanatide and lubiprostone are recommended over no drug treatment, but the evidence is moderate.[168] Tenapanor is not addressed in current guidelines because of recent FDA approval.[168] At a minimum, patients should monitor for treatment efficacy by quantifying stool frequency, the number of complete spontaneous bowel movements per week, and abdominal pain scores.[198]

TEGASEROD (ZELNORM®)

Tegaserod is a partial neuronal 5-HT4 receptor agonist that accelerates colonic peristalsis, decreases transit time, increases intestinal secretion, and reduces visceral hypersensitivity and pain.[199] Tegaserod is approved for females younger than 65 years with IBS-C, without a history of cardiovascular ischemic disease, and who have zero or one risk factor for cardiovascular disease. A dose of 6 mg orally twice daily should be administered on an empty stomach >30 minutes before a meal because its bioavailability decreases by 40% to 65% when taken with food.[200]

Tegaserod demonstrates modest but significant benefits in reducing abdominal pain, discomfort, bloating, and constipation with overall improvement in well-being in clinical trials.[199] Headache, abdominal pain, and diarrhea were the main adverse effects in trials.[200] Postmarketing analyses revealed increased incidence of heart attack, stroke, and unstable angina, resulting in halting all sales in 2007, followed by restricted use in 2009.[201] After a safety review, tegaserod was reintroduced for treating IBS-C in females.[201] Tegaserod is contraindicated in patients with a history of ischemic colitis, bowel obstruction, myocardial infarction, stroke, transient ischemic attack, angina, severe renal or hepatic impairment, or symptomatic gallbladder disease.[200] Tegaserod should be discontinued and not rechallenged in patients with new or sudden worsening abdominal pain, rectal bleeding, or bloody diarrhea indicative of ischemic colitis or other forms of intestinal ischemia.[200]

Clinicians should reserve tegaserod use for when other options for IBS-C have been exhausted.

Given that V.H. is not responding to over-the-counter laxatives, she needs a more efficacious agent. If cost and the fear of diarrhea are not significant factors, she can consider a trial of linaclotide to reduce her abdominal pain and increase complete spontaneous bowel movements. If diarrhea is a concern, trials of plecanatide or lubiprostone are reasonable choices for this patient because they may produce less diarrhea. Although tenapanor is not addressed by current guidelines, it is a viable alternative, when available in pharmacies, if linaclotide, plecanatide, or lubiprostone therapies fail. Owing to reported significant adverse effects, tegaserod can be withheld until safer therapeutic options are exhausted.

Irritable Bowel Syndrome–Associated Pain and Bloating

CASE 24-4

Question 1: L.K. is a 38-year-old female with a history of abdominal pain and episodic diarrhea. She works as a college professor. Just before teaching, she experiences "attacks" of abdominal pain and diarrhea. Her past medical history is significant for fibromyalgia and IBS-D. She takes no medications and has no known drug allergies. She denies alcohol, tobacco, or illicit drug use. She currently has two loose stools daily, with bouts of abdominal pain (severity of 7 on a 0–10 pain scale) described as "cramping" several times daily.

What pharmacologic options are available for L.K.'s abdominal pain?

ANTISPASMODICS

Antispasmodics (eg, hyoscyamine, dicyclomine, and peppermint oil) decrease GI spasticity, abdominal pain, cramping, and motility.[202,203] Clinical trials that have examined the use of these agents in IBS have been plagued by small numbers and methodologic problems. Systematic reviews have found that smooth muscle relaxants were superior to placebo in improving abdominal pain, but less effective in treating other IBS symptoms.[204] Current treatment guidelines

recommend against antispasmodics as options for pain or bloating associated with IBS.[168] If prescribed, an as-needed strategy of use has been advocated as opposed to continuous dosing owing to anticholinergic adverse effects.

ANTIDEPRESSANTS

Current treatment guidelines recommend using low-dose tricyclic antidepressants because of their analgesic effects, but selective serotonin-reuptake inhibitors are not recommended.[168] A recent meta-analysis found low-dose tricyclic antidepressants significantly improved abdominal pain, bloating, and other IBS symptoms compared with placebo.[205] A 3-month trial at a target dose should be attempted before confirming therapeutic failure. As-needed secondary amine tricyclic antidepressants (eg, doxepin, nortriptyline, desipramine) are better tolerated than are tertiary amines (eg, amitriptyline, imipramine) owing to decreased anticholinergic adverse effects such as sedation, dry mucous membranes, urinary retention, and weight gain. Clinicians can reserve tricyclic antidepressants for moderate-to-severe cases of abdominal pain and choose agents with the least anticholinergic effects for patients with IBS-C. Imipramine or amitriptyline can be recommended for patients with IBS-D.[205]

For L.K., amitriptyline 10 mg orally at bedtime can be initiated with titration to symptom relief for her moderately severe abdominal pain because she has IBS-D.

Irritable Bowel Syndrome With Diarrhea

Case 24-4, Question 2: Two weeks after L.K. was initiated on amitriptyline, she reports significant abdominal pain relief. She is sleeping better, and now rates her pain as a 2 on a 0–10 scale. Her diarrhea has improved, but she still experiences a "diarrhea attack" before each lecture. What other treatments are available for IBS-D? What are the risks and benefits of these treatments?

STANDARD ANTIDIARRHEALS

Loperamide, an opioid agonist that penetrates poorly into the central nervous system and slows accelerated small bowel and colonic transit, is the preferred agent for IBS-D because of its efficacy, cost, availability, and safety profile.[206] Loperamide improves diarrhea and global well-being.[207] As-needed dosing is preferred to scheduled dosing (eg, 2–4 mg PO up to qid as needed up to 16 mg daily), especially as prophylaxis before an identified stressful situation. Diphenoxylate with atropine is a second-line agent because of its increased risk of anticholinergic adverse effects. Cholestyramine is occasionally used in refractory cases of IBS-D, especially when bile acid malabsorption is suspected or confirmed, but it is poorly tolerated and has a substantial number of drug interactions.[208]

ALOSETRON (LOTRONEX®)

Alosetron is a highly potent 5-HT3 receptor antagonist that slows colonic motility and transit time, increases intraluminal sodium absorption, and decreases small intestinal secretions and abdominal pain.[209] Alosetron is FDA approved for females with severe IBS-D with chronic symptoms lasting 6 months or longer, who do not have anatomic or biochemical abnormalities of the GI tract, and who have not responded to conventional therapy. The starting dose for alosetron is 0.5 mg orally twice daily with or without food for 1 month. If, after 4 weeks, alosetron is well tolerated but does not control IBS symptoms, then the dosage can be increased to 1 mg twice daily.[210]

In clinical trials, alosetron was effective in improving stool consistency, frequency, and abdominal pain and discomfort as well as decreasing fecal urgency in females with IBS compared to placebo.[211] Constipation was the most frequently reported adverse effect.[211] Postmarketing reports of severe constipation with cases of bowel obstruction and ischemic colitis were reported.[212] Bowel perforation and, rarely, death were also reported, leading to withdrawal from the market in 2000. After extensive lobbying by patient groups, alosetron was reintroduced to the U.S. market in 2002 with restricted conditions for use. Prescribers must be registered with a risk evaluation and mitigation program before

prescribing alosetron, and patients must sign a patient–physician agreement and be provided with a printed medication guide. Patients must not start alosetron if they have a history of constipation, bowel obstruction, ischemic colitis, IBD, or a thromboembolic disorder.[210] A review of the mandatory postmarketing surveillance system found an overall low rate of ischemic colitis.[213] Patients must discontinue therapy if they experience constipation, new or worsening abdominal pain, or bloody stool.[210] A provider should be contacted if there is no symptom improvement after 4 weeks of use.

RIFAXIMIN (XIFAXAN®)

Rifaximin is an antibiotic that is theorized to inhibit bacterial translocation across the GI mucosa, alters the bacterial composition of gut microbiota, modulates the brain–gut axis, and reduces local inflammation.[214,215] Rifaximin is approved for the treatment of IBS-D in adults at a dose of a 550-mg tablet orally three times a day for 14 days with or without food. Patients who experience recurrence can be retreated up to two times with the same regimen.[216]

Because some evidence exists concerning an association of bacterial GI infection and IBS symptoms, some investigators suggest that small bowel flora overgrowth may contribute to IBS symptoms. Rifaximin was shown in trials to improve global symptoms in patients with IBS.[214,215,217] The size of improvement was small, but was considered clinically relevant. The most common side effects include nausea and an increase in ALT. Caution should be used when using rifaximin in patients with severe liver impairment.[216] American College of Gastroenterology guidelines recommend rifaximin to treat global IBS-D symptoms.[168] Patients should monitor for worsening diarrhea after therapy given increased risk of *C. difficile* with its use.[216]

ELUXADOLINE (VIBERZI®)

Eluxadoline is a minimally absorbed μ-opioid receptor agonist and δ-opioid receptor antagonist, in which the combination causes decreased abdominal pain, intestinal motility, and diarrhea.[218]

Eluxadoline is FDA approved for IBS-D in adults at a dose of 100 mg orally twice daily taken with food. The dose is reduced to 75 mg twice daily in patients who are unable to tolerate the original dose, have no gallbladder, have mild-to-moderate liver impairment, or are taking organic anion transporting polypeptide (OATP1B1) inhibitors.[219]

In trials, patients treated with eluxadoline had decreased abdominal pain and increase in stool consistency without significant risk of constipation.[218] The most common side effects in patients treated with eluxadoline include constipation, nausea, and abdominal pain, but the most serious is the risk of sphincter of Oddi spasm and pancreatitis among patients with a history of alcohol abuse or cholecystectomy.[219] Eluxadoline should not be used in patients with a history of bile duct obstruction, pancreatitis, severe liver impairment, and in patients who drink more than three alcoholic beverages daily.[219]

Patients should be counseled to avoid alosetron or loperamide in combination with eluxadoline use on a chronic basis because of the concern for constipation, although they can be infrequently used together as needed. Loperamide should be discontinued at once if constipation occurs. Similarly, eluxadoline requires discontinuation for constipation lasting for more than 4 days. Patients should also be recommended to avoid concomitant use of any drugs that can cause constipation (eg, anticholinergics, ferrous compounds, or opioids with eluxadoline). Pharmacists should counsel patients that eluxadoline has a potential for drug abuse.[219] At a minimum, patients should monitor for therapeutic efficacy by assessing stool consistency using the Bristol Stool Form Scale and rate their abdominal pain when it occurs.

In L.K.’s case, if dietary and other nonpharmacologic interventions fail, initiation of loperamide 2 mg as needed before lectures would be a cost-effective approach to address her symptoms. Should diarrhea worsen, or loperamide lose effectiveness, eluxadoline 100 mg twice daily with food is an alternative, whereas a course of rifaximin 550 mg tid for 14 days would be considered thereafter. The patient should combine these therapies for chronic treatment and

discontinue eluxadoline if she experiences constipation for 4 days. Alosetron is reserved only for severe cases of IBS-D.

Complications of End-Stage Liver Disease

Yasar O. Tasnif and Mary F. Hebert

CORE PRINCIPLES	CHAPTER CASES
ASCITES	
1 Cirrhosis is defined as fibrosis of the hepatic parenchyma, resulting in altered hepatic function, restricted venous outflow, and portal hypertension. Cirrhosis results in an overall vasodilated state, activation of the renin–angiotensin–aldosterone system, altered hepatic synthetic function, and development of complications such as ascites and other complications of cirrhosis.	**Case 25-1 (Question 2)**

CORE PRINCIPLES		CHAPTER CASES
2	Physical findings of ascites can include the presence of an enlarged fluid-filled abdomen, increased abdominal girth, a positive fluid wave, increased body weight, and often accompanied by peripheral edema. The goals of treatment for ascites are to mobilize ascitic fluid, diminish abdominal discomfort, as well as to prevent complications such as bacterial peritonitis and respiratory distress.	**Case 25-1 (Questions 1, 3)**
3	The treatment for ascites involves sodium restriction (2 g/day), water restriction for severe dilutional hyponatremia, and the use of spironolactone and furosemide (100:40 mg ratio). Management and monitoring of ascites includes ensuring adequate weight loss, maintaining electrolyte balance, and preventing complications of diuretic therapy.	**Case 25-1 (Questions 4–8)**

CORE PRINCIPLES		CHAPTER CASES
4	In cases of refractory ascites (diuretic-resistant), large-volume paracentesis, along with albumin replacement, is often indicated. Transjugular intrahepatic portosystemic shunt (TIPS), surgical shunts, and liver transplantation are the options for the treatment of refractory ascites when paracentesis is deemed ineffective, or in patients who are intolerant or who have a contraindication to paracentesis.	**Case 25-1 (Questions 9–11)**
5	Spontaneous bacterial peritonitis (SBP) is a common complication of ascites. Prophylactic regimens include the long-term administration of oral antibiotics such as fluoroquinolones to prevent the recurrence of SBP. Recommendations also include the administration of antibiotic prophylaxis with ceftriaxone for the prevention of SBP in patients with variceal hemorrhage.	**Case 25-2 (Question 4)**

ESOPHAGEAL VARICES

CORE PRINCIPLES		CHAPTER CASES
1	Because esophageal varices are directly related to the severity of portal hypertension, the treatment is aimed at primary prevention of bleeding by reduction of portal pressure with the use of nonselective β-blockers, such as carvedilol, and/or elimination of the varices with endoscopic variceal ligation (EVL). Treatment approaches depend on the risk of hemorrhage.	**Case 25-2 (Question 5)**
2	Secondary prophylaxis to prevent recurrent bleeding episodes includes the combination of nonselective β-blockers and EVL. TIPS may be an option in patients who experience recurrent variceal hemorrhage despite combination of pharmacologic and endoscopic therapy.	**Case 25-2 (Question 6)**

CORE PRINCIPLES		CHAPTER CASES
3	Acute variceal bleeding is considered a medical emergency and should be treated immediately. Treatment goals include volume resuscitation, acute treatment of bleeding, and prevention of recurrence of variceal bleeding. For the control and management of acute hemorrhage, the combination of pharmacologic therapy and variceal ligation is the preferred approach. In cases of acute variceal bleeding uncontrolled by pharmacologic and endoscopic therapy, TIPS can be an effective option. In certain high-risk patients, early TIPS may also be an option.	**Case 25-2 (Questions 1–3)**

HEPATIC ENCEPHALOPATHY

CORE PRINCIPLES		CHAPTER CASES
1	Hepatic encephalopathy is a metabolic disorder of the central nervous system that occurs in patients with either advanced cirrhosis or fulminant hepatic failure. The clinical features include altered mental status and asterixis. Several theories exist about the pathogenesis of hepatic encephalopathy; however, it is likely multifactorial. Precipitating causes can include gastrointestinal (GI) bleeding, diuretic-induced hypovolemia and/or electrolyte abnormalities, metabolic alkalosis, as well as sedating drugs.	**Case 25-3 (Questions 1–3)**
2	After identifying and removing precipitating causes of hepatic encephalopathy, therapeutic management is aimed primarily at reducing the amount of ammonia or nitrogenous products in the circulatory system by limiting protein intake and by the use of lactulose. Other therapeutic options include rifaximin and neomycin.	**Case 25-3 (Questions 4, 5)**
3	Monotherapy with lactulose should be tried first. If satisfactory results do not occur, switching to another option (rifaximin or neomycin) or combination therapy should be considered.	**Case 25-3 (Question 6)**

HEPATORENAL SYNDROME

CORE PRINCIPLES		CHAPTER CASES
1	Hepatorenal syndrome (HRS) is a complication of advanced cirrhosis and is diagnosed by exclusion of other known causes of kidney disease. The definitive treatment for hepatorenal syndrome-acute kidney injury (HRS-AKI, type 1 HRS) and non-AKI-HRS (type 2 HRS) is liver transplantation, which is the only treatment that assures long-term survival. The main goal of pharmacologic therapy is to reverse HRS sufficiently so that appropriate liver transplant candidates can survive until suitable donor organs can be procured.	**Case 25-3 (Questions 7, 8)**

INTRODUCTION

According to the National Vital Statistics Report published by the Centers for Disease Control and Prevention, chronic liver disease with cirrhosis is the 11th leading cause of death in the United States in non-Hispanic White, 14th in non-Hispanic Black, and 7th in Hispanic patients and accounts for ~41,571 deaths each year.[1] Cirrhosis, or end-stage liver disease, can be defined as fibrosis of the hepatic parenchyma resulting in nodule formation and altered hepatic function, which results from a variety of causes. Although there are other common causes of cirrhosis, most cases of cirrhosis worldwide result from chronic viral hepatitis or chronic alcohol consumption.[2] This chapter describes the pathogenesis of cirrhosis and the associated complications of portal hypertension (esophageal varices, gastric varices, ascites, spontaneous bacterial peritonitis

[SBP], hepatic encephalopathy [HE], and hepatorenal syndrome [HRS]) and their treatment.

PATHOGENESIS OF CIRRHOSIS

The liver consists of the hepatic parenchyma (hepatocytes) and a large proportion of nonparenchymal cells, including sinusoidal endothelial cells, Ito cells, and macrophages. Most of the liver's role in detoxification takes place within the hepatocytes. Also within the liver is the biliary tree in which bile drains from the liver and some substances are actively transported into the bile.[3] The liver has the capacity to regenerate; however, ethanol and hepatitis viruses can impair regeneration.[4]

Liver injury leading to cirrhosis impairs hepatic function. Steatosis from ethanol is characterized by lipid deposition in the hepatocytes, which is followed by liver inflammation (steatohepatitis), hepatocyte death, and collagen deposition leading to fibrosis.[5] Oxidative stress appears to play a role in alcohol-induced liver injury. It is important to note that not all heavy drinkers experience liver cirrhosis.[6] Factors such as sex, genetic risk factors, diabetes, obesity, cigarette smoking, and chronic viral infection may also play a role in the development and progression of alcohol-related liver disease.[7]

Hepatitis C virus (HCV) affects millions of people worldwide. If left untreated, approximately a half to two-thirds of those chronically infected are predicted to progress to cirrhosis, and about 3% of patients with cirrhosis progress to hepatocellular carcinoma.[8] The progression of liver disease in patients with HCV is dependent on both patient and viral factors. Multiple mechanisms are proposed to play a role in liver injury associated with HCV infection, such as diminished immune clearance of HCV, oxidative stress, hepatic steatosis, increased iron stores, and increased rate of hepatocyte apoptosis.[9] Because not all patients infected with HCV experience cirrhosis, factors other than viral clearance, such as individual immune response, age, sex, hepatic iron content, alcohol

consumption, and HCV genotype, are all implicated as cofactors in the development of cirrhosis.[10]

Among other causes, autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis, biliary atresia, metabolic disorders (eg, Wilson disease and hemochromatosis), chronic inflammatory conditions (eg, sarcoidosis), and vascular derangements can lead to hepatic fibrosis and cirrhosis.[2] Approximately 20% of Americans have nonalcoholic fatty liver disease (NAFLD), which in most cases has no symptoms. Risk factors commonly associated with the development of NAFLD include obesity, hyperlipidemia, and diabetes. Although corticosteroids can cause fatty liver, NAFLD diagnosis excludes corticosteroids and other causes of fatty liver. Nonalcoholic steatohepatitis (NASH) is a more serious form of NAFLD, which can lead to cirrhosis. Evidence suggests that insulin resistance and lipid peroxidation play a role in the pathogenesis of this condition.[11,12] Regardless of the cause of end-stage liver disease, the most frequent complications of portal hypertension are esophageal or gastric varices, ascites, HE, and HRS.[13]

COMPLICATIONS OF CIRRHOSIS

Portal Hypertension

The portal vein begins as a confluence of the splenic, superior mesenteric, inferior mesenteric, and gastric veins and ends in the sinusoids of the liver (**Fig. 25-1**). Blood in the portal vein contains substances absorbed from the intestine and delivers these substances to the liver to be metabolized before entering the systemic circulation. Once the portal blood reaches the liver, it crosses through a high-resistance capillary system within the hepatic sinusoids.

Figure 25-1 Schematic diagram of the portal venous system.

In cirrhosis, increased intrahepatic resistance results from intrahepatic vasoconstriction that is hypothesized to be caused by a deficiency in intrahepatic nitric oxide (NO).[14] Increased intrahepatic resistance also results from an enhanced activity of vasoconstrictors and structural changes from liver regeneration, sinusoidal compression, and fibrosis.

Portal hypertension results from both an increase in resistance to portal flow and an increase in portal venous inflow because of splanchnic vasodilation from increased NO production in the extrahepatic circulation.[15]

Direct portal pressure measurement is invasive and not routinely performed. The hepatic venous pressure gradient (HVPG), which reflects the gradient between the portal vein and vena cava pressure, is another accurate, safe, and less invasive procedure, widely accepted as the portal venous pressure gradient.[16–18] Normal portal pressure is generally <6 mm Hg, and in patients with cirrhosis, it may increase to 7 to 9 mm Hg. Clinically significant portal hypertension develops when portal pressure exceeds 10 to 12 mm Hg, resulting in complications such as esophageal varices and ascites.[17,19] Portal hypertension can be further classified as prehepatic (eg, splenic, portal vein thrombosis), intrahepatic (eg, hepatic cirrhosis and fibrosis), or posthepatic portal hypertension (eg, inferior vena cava obstruction, right-sided heart failure).[20–22] Persistent portal hypertension may (a) change both blood flow and the lymphatic circulation and lead to ascites formation; (b) increase pressure in the vessels that branch off the portal vein, such as the coronary veins, leading to the formation of esophageal varices; and (c) lead to the development of increased abdominal collateral circulation. HE and HRS are other complications associated with advanced cirrhosis and portal hypertension.[20–22] The American Association for the Study of Liver Diseases (AASLD) and the European Association for the Study of the Liver (EASL) Single-Topic Conference classified cirrhosis into two main categories, compensated and decompensated. Patients can be cirrhotic with a

portal pressure <10 mm Hg and an absence of the complications of cirrhosis (eg, ascites, variceal hemorrhage, or encephalopathy) and thus would be considered to be compensated. This is in contrast to a patient presenting with ascites, esophageal hemorrhage, HE, and/or HRS, which are present in decompensated cirrhosis.[23] Patients with compensated cirrhosis are managed by treatment of the underlying cause as well as prevention (primary prophylaxis) and early diagnosis of the complications. For patients with decompensated cirrhosis, the aim is to treat the complications and prevent sequela (secondary prevention).[24]

LABORATORY FINDINGS

Laboratory evaluations in cirrhosis may not reflect the extent of the parenchymal necrosis, regeneration, and fibrotic nodular scarring. Conventional liver "function" tests, such as the serum aminotransferases (aspartate aminotransferase [AST, formerly known as SGOT], alanine aminotransferase [ALT, formerly known as SGPT]) and alkaline phosphatase, are actually better characterized as liver "injury" tests and are modestly helpful to the clinician screening for hepatobiliary disease and monitoring injury progression. These tests, however, do not quantitatively measure the functional capacity of the liver. The aminotransferases are released during the normal turnover of liver cells (see Chapter 2, Interpretation of Clinical Laboratory Tests). High serum concentrations of aminotransferases suggest enzyme release from injured hepatocytes. Serum concentrations of AST and ALT may initially rise very high with acute liver injury and then fall when the etiology is removed or necrosis is so severe that few hepatocytes remain.

Because alkaline phosphatase is present in high concentrations in biliary canaliculi (as well as bone, intestines, kidneys, placenta, and white blood cells [WBCs]), its concentration increases more with biliary than hepatocellular injury. High serum concentrations of γ-glutamyl transpeptidase, alkaline phosphatase and bilirubin are suggestive of biliary injury. Elevated serum concentrations of AST

and/or ALT may suggest hepatocyte injury, but because they are also found in other tissues, their elevation is not diagnostic for liver disease.[25,26]

Serum concentrations of proteins (eg, albumin), clotting factors, prothrombin time (PT), and international normalized ratio (INR) provide some insight into liver function. Albumin is synthesized entirely by the liver; therefore, concentrations reflect hepatocellular function to some degree. However, changes in albumin concentration are nonspecific, because they are influenced by other factors, including poor nutrition, renal wasting (proteinuria), and gastrointestinal (GI) losses. PT is also nonspecific, because it is prolonged in vitamin K deficiency from poor nutrition or fat malabsorption as well as biliary obstruction (cholestasis).[27]

A number of the factors described earlier are included in the Child–Turcotte–Pugh classification of liver disease severity (**Table 25-1**).[28,29] This scoring system helps clinicians grade disease severity, and predicts the long-term risk of mortality and quality of life. A person with Child–Turcotte–Pugh class A cirrhosis may survive 15 to 20 years, whereas those with class C may survive only 1 to 3 years.[30] The main limitation of the Child–Turcotte–Pugh classification is the subjective nature of some factors, such as ascites and HE, which are subject to clinical interpretation and may be altered by therapy.[31,32] As a general guide, and not a rule, class A patients are considered to be compensated, and classes B and C decompensated.[24]

Table 25-1
Child–Turcotte–Pugh Classification of Severity of Liver Disease

	Score[a]		
	1 Point	2 Points	3 Points
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
INR	<1.7	1.7–2.3	>2.3
Ascites	None	Mild to moderate	Severe
Encephalopathy (grade)	None	Mild to moderate (1 and 2)	Severe (3 and 4)

INR, international normalized ratio.

[a]Class A, 5–6 points; class B, 7–9 points; class C, 10–15 points.

An alternate method for assessing survival in patients with liver disease is the Model for End-Stage Liver Disease (MELD) score, which is calculated by the following formula[32]:

$$\begin{aligned}\text{MELD score} = {} & 9.6 \times \log(\text{serum creatinine mg/dL}) + 3.8 \\ & \times \log(\text{serum bilirubin mg/dL}) \\ & + 11.2 \times \log(\text{INR}) + 6.4\end{aligned}$$

(Eq. 25-1)

Because of the good correlation between the MELD score and short-term (3-month) mortality, as well as the objective nature of the system, it replaced the Child–Turcotte–Pugh score in the United Network for Organ Sharing (UNOS) prioritization of organ allocation of cadaveric livers for transplantation.[33–35] Hyponatremia is common in patients with cirrhosis. Because lower serum sodium levels are a marker of the severity of cirrhosis, in January 2016, UNOS adopted serum sodium as a factor in the calculation of the MELD score[32]:

$$\text{MELD-Na} = \text{MELD} + 1.32 \times (137 - \text{Na}) - [0.033 \times \text{MELD} \times (137 - \text{Na})]$$

(Eq. 25-2)

The UNOS policy states that candidates with an initial MELD score >11 have their score recalculated utilizing the MELD-Na equation. Candidates with hyponatremia may benefit from this recalculation, because it can increase their MELD score and, therefore, priority for transplantation.[32]

MELD scores range from 6 (less ill) to 40 (gravely ill), with highest scores given priority for organ allocation with the exception of Status 1A adult patients (acute and severe onset of liver failure, who have a life expectancy of hours to a few days without liver transplantation) who are given highest priority.[36]

CLINICAL PRESENTATION

CASE 25-1

QUESTION 1: R.W. is a 54-year-old male with a 2-week history of nausea, vomiting, and lower abdominal cramps without diarrhea. Despite chronic anorexia, he has managed to drink a fifth of vodka (750 mL) and eat about two meals a day for the past 2 years. During this time, he experienced a 30-pounds (13.60 kg) weight loss. He began drinking 9 years ago when his wife became disabled after diagnosis of a brain tumor. Two years ago, his alcohol consumption increased from one pint to a fifth daily. Recently, he has noted bilateral edema of his legs, an increased tenseness and girth of his abdomen, jaundice, and scleral icterus. His medical history is noncontributory, other than a history of SBP 6 months ago. He is not taking any medications and has no known drug allergies.

Physical examination reveals an afebrile, jaundiced, and cachectic male in moderate distress. Spider angiomas were found on his face and upper chest. In addition, palmar erythema was noted.

Abdominal examination reveals prominent veins on a very tense abdomen. The liver edge is percussed below the right costal margin and ascites is noted by shifting dullness and a fluid wave. The spleen is not palpable. On neurologic examination, R.W. is awake and oriented to person, place, and time. Cranial nerves II to XII are grossly intact, but a decrease in vibratory sensation of the lower extremities is noted bilaterally. Admission laboratory data are as follows:

Sodium, 135 mEq/L
Chloride, 95 mEq/L

Potassium, 3.8 mEq/L
Bicarbonate, 25 mEq/L
Blood urea nitrogen (BUN), 15 mg/dL
Serum creatinine (SCr), 1.4 mg/dL
Glucose, 136 mg/dL
Hemoglobin (Hgb), 11.2 g/dL
Hematocrit (Hct), 33.4%
AST, 212 IU
ALT, 110 IU
Alkaline phosphatase, 954 IU
PT, 13.5 (INR, 1.1)
Total/direct bilirubin, 18.8/10.7 mg/dL
Albumin, 2.3 g/dL
Guaiac-positive stools

On admission to the hospital, the impression is alcoholic cirrhosis, ascites, and heme-positive stools.

What subjective and objective evidence are compatible with alcoholic cirrhosis in R.W.?

R.W.'s liver function tests (elevated ALT, AST, alkaline phosphatase, and bilirubin) and physical findings (enlarged, palpable liver edge; jaundice; spider angiomas; palmar erythema; and cachexia) are consistent with advanced alcoholic cirrhosis in a patient with a history of chronic alcohol abuse. The prolonged PT and hypoalbuminemia suggest impaired hepatic synthesis of both albumin and vitamin K–dependent clotting factors. The low albumin contributes to both ascites and edema. The bilirubin of 18.8 mg/dL suggests that vitamin K absorption may be a factor in the prolonged PT. The presence of ascites (an enlarged fluid-filled abdomen) and prominent abdominal veins is suggestive of portal hypertension. A biopsy of the liver may establish the presence and severity of cirrhosis. R.W.'s prolonged PT, however, will increase the risk of bleeding from a liver biopsy. His positive guaiac finding could be indicative of bleeding esophageal varices or from another GI source. This needs to be confirmed by endoscopy. He is oriented to person, place, and time, but full HE evaluation is needed. R.W.'s calculated MELD score is 23, which predicts a 90-day mortality of ~20%.[33] A patient's MELD score may increase or decrease for a period of time depending on the patient's clinical status and treatment. A number of

MELD scores will be calculated if R.W. is listed as a transplantation candidate to determine his status for organ allocation.[36] Muscle wasting and poor nutrition are the most common causes of weight loss in patients with alcohol-related cirrhosis (see Chapter 90, Substance Use Disorders).

ASCITES

Pathogenesis of Ascites

Case 25-1, Question 2: What physiologic mechanism predisposes R.W. to fluid accumulation in the peritoneal cavity?

Ascites, or accumulation of fluid in the peritoneal cavity, is the most commonly encountered clinical symptom of cirrhosis.[24,37] This complication can be detected during physical examination when >3 L of fluid has accumulated. In addition to an obviously enlarged abdomen, R.W. was found to have a positive fluid wave and shifting dullness, indicating that the abdominal enlargement is not simply obesity. If the diagnosis is in doubt, which sometimes occurs in patients with obesity, ascites can be confirmed with ultrasound. Generally speaking, in obesity the abdomen enlarges over time (months to years), in contrast to ascites where abdominal enlargement can occur over a few weeks.[38] Once ascites develops, the 1-year patient survival rate falls to ~50%.[24]

In cirrhosis, high hepatic venous pressure leads to high intrasinusoidal pressure and development of ascites across the hepatic capsule.[39] The systemic compensation to the generalized vasodilation in cirrhosis is increased cardiac output as well as sodium and water retention through activation of the renin–angiotensin–aldosterone system (RAAS).[40] R.W.'s hypoalbuminemia (2.3 g/dL), RAAS activation, exudation of fluid from the splanchnic capillary bed and the liver surface when the drainage capacity of the

lymphatic system is exceeded, and decreased ability of fluid to be contained within the vascular space owing to impaired hepatic albumin synthesis contribute to the development of ascites.

Goals of Therapy

Case 25-1, Question 3: What are the therapeutic goals in the treatment of R.W.'s ascites?

The goals of treatment for R.W.'s ascites are to treat the cause of cirrhosis by ceasing alcohol consumption; mobilize ascitic fluid; diminish abdominal discomfort, back pain, and difficulty ambulating; as well as prevent complications (eg, bacterial peritonitis, hernias, pleural effusions, HRS, and respiratory distress).[38] After the initial resolution of significant edema, the weight loss goal is 1.10 pounds/day (0.5 kg/day), which corresponds to a net fluid volume loss of ~0.5 L/day. Treatment of ascites in R.W. should be undertaken cautiously and gradually because acid–base imbalances, hypokalemia, or intravascular volume depletion caused by overly aggressive therapy can lead to compromised renal function, HE, and death.[41,42] The initial medical management of ascites involves restriction of sodium intake and the use of diuretics to promote salt and water excretion.[38]

Fluid and Electrolyte Balance

URINARY Na:K RATIO

Case 25-1, Question 4: The 24-hour urinary electrolytes for R.W. were as follows:

Na, 10 mEq/L
K, 28 mEq/L

Why would sodium or water restriction be appropriate (or inappropriate) for R.W.?

Normally, urine electrolytes mirror serum electrolytes (ie, sodium concentration is greater than that of potassium). A reversal of this pattern (ie, potassium exceeding sodium) may indicate a relative hyperaldosteronism secondary to diminished renal blood flow and low oncotic pressure. A small study by Trevisani et al[43] evaluated renal sodium and potassium handling and plasma aldosterone in a 24-hour period in cirrhotic patients without ascites, with ascites, and healthy controls. Plasma aldosterone was significantly higher in patients with ascites, resulting in reduced renal sodium excretion and more than doubling renal potassium excretion in comparison to healthy controls.[43] For urine electrolyte monitoring to be meaningful, the first sample must be obtained before initiating diuretics.[44,45]

SODIUM RESTRICTION

Although serum sodium in patients with ascites is often low, they are total body sodium overloaded. Sodium restriction has been shown to enhance mobilization of ascites, because fluid loss and weight change are directly related to sodium balance in patients with portal hypertension–related ascites.[46] This finding has been incorporated into the AASLD guidelines for the treatment of ascites. The AASLD recommends that dietary sodium should be restricted to 2000 mg/day (88 mmol/day) and R.W. should be advised to limit his sodium intake accordingly.[38] Historically, bed rest has been advocated; however, no controlled trials support this practice.[38,42]

WATER RESTRICTION

A large prospective, observational study[47] reported that hyponatremia (sodium <135 mEq/L) is common in patients with cirrhosis, associated with poor ascites control and a greater frequency of HE, HRS, and SBP compared to patients with normal serum sodium concentrations.[47] In addition, very low serum sodium concentrations (<120 mEq/L) are independent from the MELD score in predicting 3- to 6-month mortality. The AASLD recommends that water restriction should be implemented in patients with cirrhosis who have severe dilutional hyponatremia (serum Na <125 mEq/L).[38]

Water restriction is not indicated for R.W. at this time because his serum sodium concentration is within normal limits (135 mEq/L).

VASOPRESSIN RECEPTOR ANTAGONISTS

A complete discussion of vasopressin receptor antagonists can be found in Chapter 27, Fluid and Electrolyte Disorders. The AASLD guidelines do not recommend the use of vasopressin (V2) receptor antagonists because of the lack of evidence of efficacy in patients with cirrhosis, side effects, as well as the low cost-effectiveness of these medications.[38] However, it is possible that with more evidence from clinical trials, this class of medications may find a niche in the treatment of hyponatremia in patients with cirrhosis.

Diuretic Therapy

CHOICE OF AGENT

Case 25-1, Question 5: R.W. was prescribed sodium restriction after initial evaluation. Spironolactone 100 mg/day and furosemide 40 mg/day were ordered to induce diuresis. Why is spironolactone preferred over other diuretics in the treatment of ascites?

Most patients with cirrhosis have elevated plasma concentrations of aldosterone.[48] High serum concentrations of aldosterone may be attributed to both increased production and decreased excretion of the hormone. Increased portal pressure, ascites, depletion of intravascular volume, and decreased renal perfusion can lead to activation of the RAAS.[49] In addition, hepatic shunting also increases aldosterone production by decreasing renal blood flow.[50] The liver metabolizes aldosterone, and hepatic impairment prolongs the physiologic half-life of aldosterone.[51] The AASLD consensus guidelines recommend the use of spironolactone as the initial diuretic of choice in the treatment of ascites.[38] Although no large comparative studies have evaluated different diuretics as first-line treatment of ascites, spironolactone is a rational diuretic choice for

R.W. based on its aldosterone antagonist activity. Perez-Ayuso et al[52] conducted a small randomized trial to study the efficacy of furosemide versus spironolactone in non-azotemic cirrhotic patients with ascites. They reported a higher response to spironolactone than furosemide (18/19 vs 11/21; $P < .01$). Of the 10 nonresponders to furosemide, 9 responded to spironolactone. The authors also found that patients with higher renin and aldosterone levels did not respond to furosemide and required higher doses of spironolactone to achieve a diuretic response.[52]

Some clinicians may initiate spironolactone at a dose of 25 mg once or twice daily; however, much larger doses (100–400 mg/day) are generally necessary to antagonize the high circulating levels of aldosterone in patients with ascites.[38] The diuretic effect is enhanced when spironolactone is combined with sodium restriction.[42] In addition, furosemide can be started to minimize the risk of hyperkalemia and enhance diuresis. The AASLD guidelines recommend starting spironolactone 100 mg and furosemide 40 mg/day simultaneously and maintaining a 100:40 mg ratio. The doses of both oral diuretics can be increased simultaneously every 3 to 5 days (maintaining the ratio) to achieve adequate response. Usual maximal doses are 400 mg/day of spironolactone and 160 mg/day of furosemide.[38] In patients without renal failure, sodium restriction and diuretic therapy are effective in 90% of patients with ascites.[38,53]

Triamterene and amiloride can be used as alternatives to spironolactone if intolerable side effects (eg, gynecomastia) occur with spironolactone.[54,55] In a small trial,[56] non-azotemic cirrhotic patients with ascites were randomly assigned to receive amiloride (20–60 mg/day) or potassium canrenoate (150–500 mg/day, an active metabolite of spironolactone not available in the United States). A higher response rate was seen in the canrenoate group versus the amiloride group (14/20 vs 7/20; $P < .025$). The authors also assessed plasma aldosterone activity and found that all responders to amiloride had normal plasma aldosterone concentrations, and all nonresponders to amiloride who later

responded to potassium canrenoate had increased levels of plasma aldosterone.[56]

Eplerenone (a selective aldosterone blocker, more specific for the aldosterone receptor with a lower affinity for progesterone and androgen receptors than spironolactone) has been studied in patients with heart failure, hypertension, and renal disease.[57,58] The usual dose for eplerenone is 25 to 50 mg/day, with no dosage adjustment needed in mild-to-moderate liver disease. However, severe liver disease has not been studied.[59] Interestingly, a study by Sehgal et al utilized a higher dose of eplerenone (100 mg/day) in patients with cirrhosis and showed significantly higher weight reduction compared to patients taking 50 mg/day ($P < .001$).[60] Approximately 10% of patients treated with spironolactone develop gynecomastia or breast pain, with 2% requiring drug discontinuation.[61] In contrast, gynecomastia occurs at a similar rate with eplerenone as with placebo (0.5%).[62,63] Unfortunately, eplerenone is much more expensive than spironolactone.[63] The lower risk of gynecomastia with eplerenone may make it a useful alternative to spironolactone; however, given its higher cost and the lack of data in the treatment of ascites in patients with severe liver disease, its role in ascites treatment remains unclear.

R.W. should receive spironolactone 100 mg and furosemide 40 mg simultaneously (maintaining a 100:40 mg ratio) as recommended by the AASLD.[38] R.W. should be carefully monitored for diuretic complications and clinical response (see Case 25-1, Questions 6–8).

MONITORING

Clinical responses

Case 25-1, Question 6: What clinical responses should be monitored to ensure the therapeutic effectiveness of spironolactone therapy for R.W.?

Because ascitic fluid is slow to reequilibrate with vascular fluid, diuresis >0.5 to 1 kg/day (>0.5–1 L) may be associated with volume depletion, hypotension, and compromised renal function.[38] Patients

may tolerate a faster diuresis if peripheral edema is present. Once edema has resolved, a scaled-back weight loss, not to exceed 1.10 pound/day (0.5 kg/day), can be used as a rule of thumb to minimize the risk of renal insufficiency induced by plasma volume contraction and other diuretic-induced complications.[38,64] Body weight and abdominal girth are routinely monitored in both the inpatient and outpatient settings. Fluid intake and urine output are monitored primarily for inpatients, owing to practical constraints in the outpatient setting. Ideally, urine output should exceed fluid intake by about 300 to 1000 mL/day. These measurements do not account for nonrenal fluid losses; therefore, total fluid loss will be somewhat higher. Abdominal girth measurement (circumference around the abdomen) is subject to error, because of its dependence on patient position and measurement location on the abdomen.[65] Attempts should be made to standardize patient position (eg, sitting at a 45° angle) and location of measurement (level of umbilicus) to minimize variability in abdominal girth measurements.

Laboratory parameters

Case 25-1, Question 7: What laboratory parameters could be monitored to assess the therapeutic efficacy of R.W.'s spironolactone treatment?

Serum concentrations of creatinine and urine chemistries (sodium and potassium) can be monitored to define and guide the need for dosage adjustment of spironolactone. A low baseline urine Na:K ratio (<1.0) suggests high intrinsic aldosterone activity and that a larger dosage of spironolactone may be needed, as is the case for R.W. If necessary, the dosage of diuretic therapy may be doubled after a few days.[49] AASLD recommends increasing both spironolactone and furosemide simultaneously every 3 to 5 days (maintaining a 100:40 mg ratio) to achieve adequate diuresis and maintain a normal serum potassium.[38]

DIURETIC COMPLICATIONS AND MANAGEMENT

Case 25-1, Question 8: The spironolactone and furosemide dosages were increased to 200 and 80 mg/day (maintaining a 100:40 mg ratio). What potential complications from the diuretic therapy might arise in R.W. and how can they be minimized?

Electrolyte and acid–base disturbances

Hyponatremia, hyperkalemia, metabolic alkalosis, and, uncommonly, hypokalemia occur as side effects of diuretic therapy in patients with ascites. Hyponatremia results from a reduction in free water clearance (dilutional hyponatremia). Diuresis exacerbates hyponatremia by causing volume depletion and antidiuretic hormone (ADH) release. Hyponatremia usually can be corrected by temporary withdrawal of diuretics and free water restriction.[53,66–68] Although serum sodium may be low, these patients are total body sodium overloaded. Hyperkalemia is common in patients with refractory ascites and impaired renal function requiring high doses of diuretics such as spironolactone. Hyperkalemia can be approached in multiple ways, depending on the clinical situation (see Chapter 27, Fluid and Electrolyte Disorders). Furosemide is added to spironolactone to maintain normal serum potassium.[38] Decreasing or holding spironolactone may be appropriate depending on the patient's renal function and serum potassium.[24] Metabolic alkalosis, a result of loop diuretics, occurs because of increased urinary hydrogen loss from enhanced distal hydrogen secretion. Hypokalemia often accompanies metabolic alkalosis owing to loop diuretics.[67] Furosemide can be temporarily withheld in patients presenting with hypokalemia.[38] R.W. has some degree of renal impairment (SCr, 1.4 mg/dL) and is receiving spironolactone and furosemide. Therefore, his electrolytes and renal function tests should be monitored daily while hospitalized. After hospital discharge, monitoring will be dictated by the stability of the patient and need for diuretic dosage adjustments. For example, outpatients may need electrolytes and renal function monitoring once or twice weekly early after hospital discharge to as infrequently as every 3 months for very stable patients.[38]

Prerenal azotemia

Prerenal azotemia usually results from overdiuresis with subsequent compromise of intravascular volume and decreased renal perfusion. In addition to looking for clinical signs of hypovolemia, such as dizziness, orthostatic hypotension, and increased heart rate, frequent measurements of BUN and SCr concentrations provide a relatively simple means of assessing the intravascular volume. A gradual rise in SCr, BUN, as well as the BUN:SCr ratio can serve as a warning to slow the rate of diuresis.[69] In a small study,[64] serial measurements of plasma volume and ascites volume were made during treatment with diuretics in patients with cirrhosis. Patients with ascites and no edema were able to mobilize >1 L/day during rapid diuresis, but at the expense of plasma volume contraction and renal insufficiency. Patients with peripheral edema appear to be somewhat protected from these effects and may safely undergo diuresis at a more rapid rate (>2 kg/day) until edema resolves.[64] Others suggest, however, that the maximal daily fluid loss should not exceed >0.5 L/day (>0.5 kg/day) for patients with ascites alone or 1 L/day (>1 kg/day) for those with both ascites and edema to prevent plasma volume depletion and decreased renal perfusion. If faster removal of ascites is required because of respiratory distress, large-volume paracentesis may be more effective than rapid diuresis (see Case 25-1, Question 9).[38,45,70,71] In patients with cirrhosis, azotemia may also occur because of nonsteroidal anti-inflammatory drugs (NSAIDs). All NSAIDs should be discontinued, except low-dose aspirin in patients at high risk for a cardiac or neurologic event.[38]

Because R.W. presented with both edema and ascites, an initial weight loss of up to 2.20 pounds/day (1 kg/day) would be reasonable with slowing to 1.10 pound/day (0.5 kg/day) when the edema resolves. Gradual diuresis avoids diuretic-induced depletion of intravascular fluid volume by permitting ascitic fluid to equilibrate with intravascular fluid. Long-term management of ascites is done in the outpatient setting. Severe cases with respiratory distress or impaired ambulation as well as patients with SBP (see Chapter 70, Intra-Abdominal Infections) require hospitalization. If outpatient therapy is

an option, a weekly evaluation initially would be prudent to prevent overdiuresis and electrolyte disturbances.[38]

Refractory Ascites

Case 25-1, Question 9: Over the next several days, R.W.'s spironolactone dosage was increased to 400 mg/day. Furosemide was simultaneously increased to 80 mg bid without major improvement in diuresis. Laboratory data revealed that R.W.'s SCr had increased to 3.2 mg/dL (estimated creatinine clearance: 26 mL/minute) and his BUN had increased to 45 mg/dL. Serum electrolytes were as follows:

K, 3.1 mEq/L
Na, 130 mEq/L
Cl, 88 mEq/L
Bicarbonate, 32 mEq/L
